In order to describe the design of an options format, we distinguish several classes of solver options. First, options may apply to the problem instance. For example, the MPS input format does not allow specifying the direction of optimization (min or max). Solver options (so called *agenda cards*) [16] can be used to communicate this information.

A second category of options controls the flow of the solution algorithm. In this category, there are options to select a particular algorithm class (e.g., primal simplex, dual simplex or interior point method in a linear program) or algorithm variant (for instance a particular pricing scheme). Options such as whether to scale a coefficient matrix or not, which crashing and preprocessing procedures to use, as well as limits on the number of iterations or the solution time, would also fall into this category. For nonlinear problems, one can also specify an initial point.

Other solver options include various tolerances, the amount and type of output generated (including the level of diagnostic messages when parsing the input), the location and name of input and output files, whether the solution needs to be saved for subsequent runs, perhaps with modified data, and so on. It does not stop there. Especially in distributed computing, it may be necessary to control the environment in which the solution is obtained. For example, it may be known that the solution of an

instance places space requirements on a server, which may limit the choice of servers that could potentially be used.

The optimization services option language (OSoL) schema is to our knowledge the first attempt at standardizing the specification of solver and process options [27,28]. We end this section with a small file in the OSoL format (Fig. 4). This file should be self-explanatory. It first specifies that the job is to be run only on computers with at least 1 Gb of memory, provides initial values for two decision variables, and gives four solver options. Two of these options are intended for the Ipopt solver [29]; the other two are for the LINDO solver [30]. This demonstrates that an option file can be shared between different solvers. The two Ipopt options control the amount of output to be generated and where the output is to be directed; the LINDO options illustrate that the same option can be used with different scope, applying to a single model in the first case and to the entire session in the second case.

SOLVER RESULT INSTANCE FORMAT

It is necessary for an optimization solver to communicate the solution result back to the user. Most solvers have their own result format or API for communicating the solution result. Although not nearly as widespread as the MPS instance format, there is also an MPS format for reporting solver results [16]. The MPS result format is a table-based one and separated into three sections: header, rows, and columns. The header section lists such information as problem instance name, objective value, status, and number of iterations. The rows section provides results on the constraints such as constraint values, slacks, and duals. The columns section provides results on the variables such as solution values and reduced costs. The two major problems with the MPS result instance format are that it is optimization-centric and is not easily extensible.

An alternative result instance format is OSrL (optimization services result language) [27,28]. OSrL supports multiple solutions with multiobjectives. Each solution contains

```

    </solverOptions>
  </optimization>
</osol>

```

Figure 4. A sample OSoL file.

a separate set of variable, objective, constraint, and other results. For results that are uncommon, or solver specific, or subject to different interpretations, OSrL provides the mechanism of `otherSolutionResult` and `otherSolverOutput`. We show below a small segment of OSrL from an actual application that illustrates “nonstandard” solver output that is important to communicate (Fig. 5).

In addition to the optimization category, which communicates output directly related to the optimization solution, the OSrL format contains four further categories: general, system, service, and job. The general result section contains such information as general status and message, service name and uniform resource identifier (URI); instance name, job ID,

solver invoked, and time stamp. The system section contains information about available disk space, memory, and CPU. The service section contains information about the host optimization service, such as its current state (busy or idle) and service utilization. The job section contains information about the particular optimization job process such as its submit/scheduled/start/end time, as well as CPU, disk, and memory usage. Each of these sections provides the “other” mechanism for custom results.

EXTENSIONS

If a problem instance format is well designed, it should be flexible enough to extend the

standard “core” optimization types such as continuous and mixed integer linear, quadratic, and general nonlinear programs. In this section we list potential extensions to the core instance format. It is critical that the core instance format is not affected by the extensions and that whenever a new optimization type is added, the core format remains unchanged, keeping the standards backward compatible.

1. **Logic and Constraint Programs.** If the instance format has a built-in nonlinear expression tree, it should be quite natural for it to be extended to this type of programs, as logic and relational operators are expressed in the same way as all regular nonlinear operators. For example `if` is simply an operator that takes three operands. Constraint programs use other special operators such as `and`, `or`, `xor`, `not`, `if`, `implies`, `eq`, `neq`, `geq`, `gt`, `leq`, `lt`, and `alldiff`.
2. **Complementarity Problems.** Similar to extending the logic and constraint programs, we can add a `complements` operator to express such problems. The `complements` operator takes two operands. Each operand must be either an inequality or an equality operand (in which case the condition is redundant). The `complements` operator evaluates to true if both operands are true and at least one inequality is tight.
3. **Special ordered sets (SOS).** There are several types of SOS [31–34], but each type is essentially expressed as a set of indices of variables already defined in the core programs, plus optional information such as a convexity row.
4. **Semicontinuous Constraints (SC).** These are typically constraints on variables that require the value of a variable to either be equal to 0 or lie between a lower and upper bound where the lower bound is greater than zero.
5. **Cone Programs.** There are many widely used cone types including nonnegative cone, quadratic cone, rotated quadratic cone, and semidefinite cone [35].
6. **Disjunctive Programs.** Among all the possible extensions, the disjunctive program extension is probably the one that benefits the most from building on the core, as almost all the data have already been represented in the core and each disjunction usually just alters a tiny piece of information from the core; for example, change of a matrix coefficient or constraint bound. Each disjunction is essentially trying to construct a separate problem instance with the least amount of extra data.
7. **Robust Optimization and Stochastic Optimization.** These are two ways for dealing with uncertainty in the problem parameters. Robust optimization can be thought of as a special case of stochastic programming, and it is a design choice whether to define it as a separate extension or just subsume it under the more general heading of stochastic programming.
8. **Instance Modification.** Popular algorithms such as branch-cut-and-price often require addition or deletion of constraints and variables. Currently there is no instance format for specifying model changes.
9. **Real-Time Data.** In a tightly coupled modeling environment, a modeler creates a problem instance using a modeling language. The instance file is self-contained and has all of the parameters necessary for optimization by a solver. However, as data are updated in real time, it is desirable from an efficiency standpoint to update only the data that have changed and not regenerate the entire instance.
10. **User-Defined Functions.** No matter how many nonlinear operators and functions an instance format supports, it cannot exhaust all of them and should support custom-defined functions, to be used in the nonlinear expression tree along with other standard functions.
11. **Optimization via Simulation.** Not all functions (constraints or objectives) have explicit forms and if the function

is a black box simulation that cannot be easily modeled by any user function, one needs the support of optimization via simulation.

12. Network and Graph Problems. Network and graph problems traditionally are built around the concepts of *vertices* and *arcs*, instead of *constraints* and *variables*. Special formats may be needed to deal with them effectively.
13. Instance Communication over a Network. Given the trend toward cloud computing and computing on demand, there will almost certainly be a need to communicate instance formats over a network. The optimization problem, solver options, and solver results, along with header information, must all be packed in the body of a larger “instance” that is communicated over a network. For a discussion of higher-level network instance formats for optimization see Refs 27 and 28.
14. Optimization over Vector Spaces. Discrete-time optimal control problems are often merely an approximation of an underlying continuous-time problem. The discretization step is arbitrary and should occasionally be allowed to be refined by the solution algorithm. It would therefore be useful to have a way to express the underlying continuous-time problem directly.

INTRODUCTION

This article describes what is known about duality for integer programs. It is perhaps surprising that many of the results familiar from linear programming (LP) duality do extend to integer programming. However, this generalization requires adoption of a more general point of view on duality than is apparent from studying the linear programming case. Duality theory, as we shall define it here, is generally concerned with the development of methods for determining the effect on the optimal solution value of perturbations in the right-hand side of a mathematical program, which can be thought of as specifying the resources available to operate a system. The study of duality is hence the study of a parameterized family of mathematical programming instances and is closely related to parametric programming and sensitivity analysis. More formally, duality theory can be thought of as the study of the so-called *value function*, which is a function that takes a right-hand side vector as input and returns the optimal solution value of one of a family of integer programming instances parameterized by that right-hand side vector. In the linear programming case, the value function is piecewise linear and convex (assuming minimization), which is the reason for the tractability of the linear programming dual problem. In the integer programming case,

the value function has a more complex structure, as we shall see.

In this article, we consider a mixed integer linear program (MILP) (referred to as the *primal problem*) of the form

$$z_{\text{IP}} = \min_{x \in S} cx, \quad (1)$$

where $c \in \mathbb{R}^n$ is the objective function vector and the feasible region

$$S = \{x \in \mathbb{Z}_+^r \times \mathbb{R}_+^{n-r} \mid Ax = b\} \quad (2)$$

is defined by a constraint matrix $A \in \mathbb{Q}^{m \times n}$ and a right-hand side vector $b \in \mathbb{R}^m$. Note that for simplicity of notation, we omit the transpose symbol for the inner product of vectors and for matrix–vector products. By convention, $z_{\text{IP}} = \infty$ if $S = \emptyset$ and $z_{\text{IP}} = -\infty$ if for every $x \in S$, there exists $y \in S$ such that $cy < cx$. The goal is to determine z_{IP} and an *optimal solution* x^* such that $cx^* = z_{\text{IP}}$ (if z_{IP} is finite), where cx is the *solution value* of $x \in S$. The variables indexed by the set $I = \{1, \dots, r\} \subseteq N = \{1, \dots, n\}$ (if $r > 0$, otherwise $I = \emptyset$) are the *integer variables* and the remaining variables, indexed by the set $C = N \setminus I$, are the *continuous variables*. The LP obtained from a given MILP by removing the integrality requirements on the variables, that is, setting $r = 0$, is referred to as the associated *LP relaxation*. Similarly, the associated *pure integer linear program* (PILP) is obtained by requiring *all* variables to be integer, that is, setting $r = n$.

By parameterizing (1), we obtain the *value function* $z : \mathbb{R}^m \rightarrow \mathbb{R} \cup \{\pm\infty\}$ defined as

$$z(d) = \min_{x \in S(d)} cx, \quad (3)$$

where, for a given $d \in \mathbb{R}^m$, $S(d) = \{x \in \mathbb{Z}_+^r \times \mathbb{R}_+^{n-r} \mid Ax = d\}$. A *dual function* $F : \mathbb{R}^m \rightarrow \mathbb{R} \cup \{\pm\infty\}$ is a function that bounds the value function over the set $\mathbb{R}^m$, that is,

$$F(d) \leq z(d) \quad \forall d \in \mathbb{R}^m. \quad (4)$$

Figure 1. The value function and sample dual functions for (6).

Dual functions and methods for constructing them are the central focus of duality theory. The aim in constructing a dual function F is for it to closely approximate the value function z . In particular, we usually want a dual function whose value at b is as close as possible to $z(b)$. The most general form of the *dual problem* is then

$$z_D = \max \{F(b) : F(d) \leq z(d), d \in \mathbb{R}^m, \\ F : \mathbb{R}^m \rightarrow \mathbb{R}\}, \quad (5)$$

which is an optimization problem over the space of dual functions. We call F a *weak dual function* if it is feasible for (5), that is, it satisfies (4), and a *strong dual function* with respect to b if it is optimal for (5), that is, satisfies $F(b) = z(b)$. Note that we allow only real-valued functions, so that (5) is infeasible if $z_{IP} = -\infty$ and $z_D \leq z_{IP}$ otherwise. If z_{IP} is finite, the value function itself (or a real-valued extension of it) is a strong dual function, that is, $z_D = z_{IP}$.

Example 1. Consider the following MILP instance with a fixed right-hand side b :

$$\begin{aligned} \min \quad & 3x_1 + \frac{7}{2}x_2 + 3x_3 + 6x_4 + 7x_5 \\ \text{s.t.} \quad & 6x_1 + 5x_2 - 4x_3 + 2x_4 - 7x_5 = b \text{ and} \\ & x_1, x_2, x_3 \in \mathbb{Z}_+, x_4, x_5 \in \mathbb{R}_+. \end{aligned} \quad (6)$$

The value function z of this sample problem together with dual functions F_1 and F_2 are given in Fig. 1. Note that the value function is better approximated by F_1 for right-hand side values $b > 0$ and by F_2 otherwise. In addition, observe that the dual functions are strong for a subset of right-hand side values and weak otherwise.

PROPERTIES OF THE VALUE FUNCTION

The study of duality begins with the study of the value function itself. In particular, we want to know what the structure of the value function is and to what class of functions it may belong. Our first observation is that the value function is *subadditive*. A function F is *subadditive* over a domain Θ if $F(\lambda_1) + F(\lambda_2) \geq F(\lambda_1 + \lambda_2)$ for all $\lambda_1, \lambda_2, \lambda_1 + \lambda_2 \in \Theta$. The value function itself is subadditive over the domain $\Omega = \{d \in \mathbb{R}^m \mid S(d) \neq \emptyset\}$. To study this, let $d_1, d_2 \in \Omega$ and suppose $z(d_i) = cx_i$ for some $x_i \in S(d_i)$, $i = 1, 2$. Then, $x_1 + x_2 \in S(d_1 + d_2)$ and hence $z(d_1) + z(d_2) = c(x_1 + x_2) \geq z(d_1 + d_2)$. Subadditivity reflects the intuitively natural property of increasing returns to scale that we expect the value function to have.

For PILPs, Blair and Jeroslow [1] showed that a procedure similar to Gomory's cutting plane procedure can be used to construct

the value function in a finite number of steps, although the representation from this procedure may have exponential size. They were thus able to characterize the class of functions to which value functions belong, namely, *Gomory functions*, a subset of a more general class called *Chvátal functions*.

Definition 1. Let $\mathcal{L}^m = \{f : \mathbb{R}^m \rightarrow \mathbb{R} \mid f \text{ is linear}\}$. Chvátal functions are the smallest set of functions $\mathcal{C}$ such that

1. If $h \in \mathcal{L}^m$, then $h \in \mathcal{C}$.
2. If $h_1, h_2 \in \mathcal{C}$ and $\alpha, \beta \in \mathbb{Q}_+$, then $\alpha h_1 + \beta h_2 \in \mathcal{C}$.
3. If $h \in \mathcal{C}$, then $\lceil h \rceil \in \mathcal{C}$.

Gomory functions are the smallest set of functions $\mathcal{G} \subseteq \mathcal{C}$ with the additional property that

4. If $h_1, h_2 \in \mathcal{G}$, then $\max\{h_1, h_2\} \in \mathcal{G}$.

Note that both Chvátal and Gomory functions are subadditive and every Gomory function can be written as the maximum of finitely many Chvátal functions. Blair and Jeroslow [1] show for a PILP in the form (1) with $z(0) = 0$ that (i) the value function over the domain Ω is a Gomory function and (ii) there always exists an optimal solution to the dual problem (5) that is a Chvátal function.

For MILPs, Blair and Jeroslow [2] argue that the value function can still be represented by a Gomory function if $c_j = 0 \forall j \in C$ or can be written as a minimum of finitely many Gomory functions. A deeper result is contained in the subsequent work of Blair [3], who showed that the value function of an MILP can be written as a *Jeroslow formula*, consisting of a Gomory function and a correction term. For a given $d \in \Omega$, let the set $\mathcal{E}$ consist of the index sets of dual feasible bases of the linear program

$$\min \{c_C x_C : A_C x_C = d, x \geq 0\}. \quad (7)$$

By the rationality of A , we can choose $M \in \mathbb{Z}_+$ such that $MA_E^{-1}\alpha^j \in \mathbb{Z}^m$ for all $E \in \mathcal{E}$, $j \in I$, where α^j is the j th column of A . For $E \in \mathcal{E}$,

let v_E be the corresponding basic feasible solution to the dual of

$$\min \left\{ \frac{1}{M} c_C x_C : \frac{1}{M} A_C x_C = d, x \geq 0 \right\}, \quad (8)$$

which is a scaled version of (7). Finally, for a right-hand side d and $E \in \mathcal{E}$, let $\lfloor d \rfloor_E = A_E \lfloor A_E^{-1} d \rfloor$.

Theorem 1 [3]. For the MILP (1), there is a $g \in \mathcal{G}$ such that

$$z(d) = \min_{E \in \mathcal{E}} g(\lfloor d \rfloor_E) + v_E(d - \lfloor d \rfloor_E) \quad (9)$$

for all $d \in \Omega$.

THE SUBADDITIVE DUAL

The dual problem (5) is rather general, so a natural question is whether it is possible to restrict the space of functions in order to obtain a tractable method for constructing a strong dual function. Note that

$$\begin{aligned} F(d) &\leq z(d), d \in \mathbb{R}^m \\ \iff F(d) &\leq cx, x \in S(d), d \in \mathbb{R}^m \\ \iff F(Ax) &\leq cx, x \in \mathbb{Z}_+^r \times \mathbb{R}_+^{n-r}. \end{aligned} \quad (10)$$

Restricting F to be linear, (5) reduces to $\max\{vb \mid vA \leq c, v \in \mathbb{R}^m\}$ by (10), which is the dual of the LP relaxation of the original MILP. Jeroslow [4] showed that restricting the search space to only convex functions also results in the same optimal solution value as obtained in the linear case. Therefore, these restrictions result in a dual that is no longer guaranteed to produce a strong dual function.

Johnson [5–7] and later Jeroslow [8] developed the idea of restricting the search space to a certain subset of subadditive functions. It is clear that this restriction retains the desirable property of strong duality, since the value function is itself subadditive over Ω .

From (10), if we set $\Gamma^m \equiv \{F : \mathbb{R}^m \rightarrow \mathbb{R} \mid F(0) = 0, F \text{ is subadditive}\}$, then we can

rewrite (5) as the *subadditive dual*

$$\begin{aligned} z_D &= \max F(b) \\ F(\alpha^j) &\leq c_j \quad \forall j \in I, \\ \bar{F}(\alpha^j) &\leq c_j \quad \forall j \in C, \text{ and } \\ F &\in \Gamma^m, \end{aligned} \quad (11)$$

where the function $\bar{F}$ is the *upper d -directional derivative* of F at zero and is defined by

$$\bar{F}(d) = \limsup_{\delta \rightarrow 0^+} \frac{F(\delta d)}{\delta} \quad \forall d \in \mathbb{R}^m. \quad (12)$$

Intuitively, the role of $\bar{F}$ in (11) is to ensure that solutions to (11) have gradients that do not exceed those of the value function near zero, since the subadditivity of F alone is not enough to ensure this in the case of MILP.

The main results concerning the relations between the primal and dual problems in LP duality can be carried to the MILP case.

Theorem 2. *For the primal problem (1) and its subadditive dual (11), the following statements hold:*

1. (Weak duality by Jeroslow [4,8]). Let x be a feasible solution to the primal problem and let F be a feasible solution to the subadditive dual. Then, $F(b) \leq cx$.
2. If the primal problem (respectively, the dual) is unbounded then the dual problem (respectively, the primal) is infeasible.
3. If the primal problem (respectively, the dual) is infeasible, then the dual problem (respectively, the primal) is infeasible or unbounded.
4. (Strong duality by Jeroslow [4,8] and Wolsey [9]) If the primal problem (respectively, the dual) has a finite optimum, then so does the dual problem (respectively, the primal) and they are equal.

The proof of weak duality and the consequent results follow directly from the construction

of dual problem. However, in order to show that strong duality holds for the case where $\Omega \subset \mathbb{R}^m$, we need an additional result of Blair and Jeroslow [10], which states that any given MILP can be “extended” to one that is feasible for all right-hand sides and whose value function agrees with that of the original MILP for all right-hand sides $d \in \Omega$.

Example 2. For the MILP (6), the subadditive dual problem is

$$\begin{aligned} \max \quad & F(b) \\ & F(6) \leq 3 \\ & F(5) \leq \frac{7}{2} \\ & F(-4) \leq 3 \\ & \bar{F}(2) \leq 6 \\ & \bar{F}(-7) \leq 7 \\ & F \in \Gamma^1. \end{aligned} \quad (13)$$

Note from Fig. 1 that $F_2(d) = \max\{\frac{d}{2}, -\frac{3d}{4}\}$ $\forall d \in \mathbb{R}$ is feasible for the dual problem and furthermore, optimal for the right-hand side values $b \in \{\dots, -8, -4, 0, 6, 12, \dots\}$.

The subadditive dual (11) can also be used to extend familiar concepts such as *reduced costs* and the *complementary slackness* conditions to MILPs. For a given optimal solution F^* to (11), the reduced costs can be defined as $c_j - F^*(\alpha^j)$ for $j \in I$ and $c_j - \bar{F}^*(\alpha^j)$ for $j \in C$. These reduced costs have an interpretation similar to that in the LP case, except that we do not have the same concept of “sensitivity ranges” within which the computed bounds are exact. On the other hand, complementary slackness conditions, if satisfied, yield a certificate of optimality for a given primal–dual pair of feasible solutions and can be stated as follows.

Theorem 3 [7–9,11]. *For a given right-hand side b , let x^* and F^* be feasible solutions to the primal problem (1) and the subadditive dual problem (11). Then, x^* and F^* are*

optimal if and only if

$$\begin{aligned} x_j^*(c_j - F^*(\alpha^j)) &= 0, \forall j \in I, \\ x_j^*(c_j - \bar{F}^*(\alpha^j)) &= 0, \forall j \in C, \text{ and} \\ F^*(b) &= \sum_{j \in I} F^*(\alpha^j)x_j^* + \sum_{j \in C} \bar{F}^*(\alpha^j)x_j^*. \end{aligned} \quad (14)$$

The subadditive duality framework also allows the use of subadditive functions to obtain inequalities valid for the convex hull of the feasible region. It is easy to see that for any $d \in \Omega$ and $F \in \Gamma^m$ with $\bar{F}(\alpha^j) < \infty \forall j \in C$, the inequality

$$\sum_{j \in I} F(\alpha^j)x_j + \sum_{j \in C} \bar{F}(\alpha^j)x_j \geq F(d) \quad (15)$$

is satisfied for all $x \in S(d)$. Using this property, Johnson [5] and later Jeroslow [8] showed that any valid inequality for $S(d)$ is either equivalent to or dominated by an inequality in the form of (15).

As an extension to this result, Bachem and Schrader [11] showed that the convex hull of $S(d)$ can be represented using only subadditive functions and that rationality of A is enough to ensure the existence of such a representation, even if the convex hull is unbounded. For a fixed right-hand side, it is clear that only finitely many subadditive functions are needed to obtain a complete description, since every rational polyhedron has finitely many facets. In addition, Wolsey [12] showed that for PILPs, there exists a finite representation that is valid for all right-hand sides.

Theorem 4 [12]. *For a PILP in the form (1), there exist finitely many subadditive functions F_i , $i = 1, \dots, k$, such that*

$$\text{conv}(S(d)) = \left\{ x : \sum_{j=1}^n F_i(\alpha^j)x_j \geq F_i(d), \right. \\ \left. i = 1, \dots, k, x \geq 0 \right\} \quad (16)$$

for any $d \in \Omega$.

CONSTRUCTING DUAL FUNCTIONS

Dual functions can be grouped into three categories: (i) those obtained from known families of relaxations, (ii) those obtained as a by-product of a primal solution algorithm, such as branch-and-bound, and (iii) those constructed explicitly in closed form using a finite procedure.

Cutting Plane Method

Cutting plane algorithms are a broad class of methods for obtaining lower bounds on the optimal solution value of a given MILP by iteratively generating inequalities (called *cutting planes* or *cuts*) valid for the convex hull of S . In iteration k , the algorithm solves the following linear program:

$$\begin{aligned} \min \quad & cx \\ \text{s.t.} \quad & Ax = b \\ & \Pi x \geq \Pi_0 \\ & x \geq 0, \end{aligned} \quad (17)$$

where $\Pi \in \mathbb{R}^{k \times n}$ and $\Pi_0 \in \mathbb{R}^k$ represents the cutting planes generated so far. The LP dual of (17), that is,

$$\begin{aligned} \max \quad & vb + w\Pi_0 \\ & vA + w\Pi \leq c \\ & v \in \mathbb{R}^m, w \in \mathbb{R}_+^k, \end{aligned} \quad (18)$$

is also a dual problem for the original primal MILP. Assuming that a subadditive representation (15) of each cut is known, the i th cut can be expressed parametrically as a function of the right-hand side $d \in \mathbb{R}^m$ in the form

$$\begin{aligned} \sum_{j \in I} F_i(\sigma_i(\alpha^j))x_j + \sum_{j \in C} \bar{F}_i(\bar{\sigma}_i(\alpha^j))x_j \\ \geq F_i(\sigma_i(d)), \end{aligned} \quad (19)$$

where F_i is the subadditive function representing the cut, and the functions $\sigma_i, \bar{\sigma}_i : \mathbb{R}^m \rightarrow \mathbb{R}^{m+i-1}$ are defined by

- $\sigma_1(d) = \bar{\sigma}_1(d) = d$,
- $\sigma_i(d) = [dF_1(\sigma_1(d)) \cdots F_{i-1}(\sigma_{i-1}(d))] \text{ for } i \geq 2$, and

- $\bar{\sigma}_i(d) = [d\bar{F}_1(\bar{\sigma}_1(d)) \cdots \bar{F}_{i-1}(\bar{\sigma}_{i-1}(d))]$ for $i \geq 2$.

Furthermore, if (v^k, w^k) is a feasible solution to (18) in the k th iteration, then the function

$$F_{CP}(d) = v^k d + \sum_{i=1}^k w_i^k F_i(\sigma_i(d)) \quad (20)$$

is a feasible solution to the subadditive dual problem (11).

Wolsey [9] showed how to construct a dual function optimal to the subadditive dual for a given PILP using the Gomory fractional cutting plane algorithm under the assumption that cuts are generated using a method guaranteed to yield a sequence of LPs with lexicographically increasing solution vectors (this method is needed to guarantee termination of the algorithm in a finite number of steps with either an optimal solution or a proof that the original problem is infeasible). In Gomory's procedure, the subadditive function F_i , generated for iteration i , has the following form:

$$F_i(d) = \left[\sum_{k=1}^m \lambda_k^{i-1} d_k + \sum_{k=1}^{i-1} \lambda_{m+k}^{i-1} F_k(d) \right],$$

where $\lambda^{i-1} = (\lambda_1^{i-1}, \dots, \lambda_{m+i-1}^{i-1}) \geq 0$. (21)

Assuming that $b \in \Omega$, $z(b) > -\infty$, and that the algorithm terminates after k iterations, the function F_G defined by

$$F_G(d) = v^k d + \sum_{i=1}^k w_i^k F_i(d) \quad (22)$$

is optimal to the subadditive dual problem (11).

In practice, it is generally not computationally feasible to determine a subadditive representation for each cut added to the LP relaxation. An alternative approach that is feasible for some classes of valid inequalities is simply to track the dependency of each cut on the original right-hand side in some other way. As an example of this, Schrage and Wolsey [13] showed how to construct a function tracking dependency on the right-hand side for cover inequalities by expressing the right-hand side of a cut of this type as an

explicit function of the right-hand side of the original knapsack constraint.

Corrected Linear Dual Functions

A natural way in which to account for the fact that linear functions are not sufficient to yield strong dual functions in the case of MILPs is to consider dual functions that consist of a linear term (as in the LP case) and a correction term accounting for the duality gap. One way to construct such a function is to consider the well-known *group relaxation*. Let B be the index set of the columns of a dual feasible basis for the LP relaxation of a PILP and denote the index set of the remaining columns by $N \setminus B$. Consider the function F_B defined as

$$\begin{aligned} F_B(d) = \min \quad & c_B x_B + c_{N \setminus B} x_{N \setminus B} \\ \text{s.t.} \quad & A_B x_B + A_{N \setminus B} x_{N \setminus B} = d \\ & x_B \in \mathbb{Z}^m, x_{N \setminus B} \in \mathbb{Z}_+^{n-m}. \end{aligned} \quad (23)$$

Substituting $x_B = A_B^{-1}d - A_B^{-1}A_{N \setminus B}x_{N \setminus B}$ in the objective function, we obtain the group relaxation (Gomory [14]).

$$\begin{aligned} F_B(d) = c_B A_B^{-1}d - \max \quad & \bar{c}_{N \setminus B} x_{N \setminus B} \\ & A_B x_B + A_{N \setminus B} x_{N \setminus B} = d \\ & x_B \in \mathbb{Z}^m, x_{N \setminus B} \in \mathbb{Z}_+^{n-m}, \end{aligned} \quad (24)$$

where $\bar{c}_{N \setminus B} = (c_B A_B^{-1} A_{N \setminus B} - c_{N \setminus B})$. Here, dual feasibility of the basis A_B is required to ensure that $\bar{c}_{N \setminus B} \leq 0$.

Note that F_B is subadditive and hence feasible for the subadditive dual (11). Observe that $F_B(b) = z(b)$ when there exists an optimal solution to (24) with $x_B \geq 0$.

Another way to construct an optimal solution to the subadditive dual using a linear function with a correction term is given by Klabjan [15].

Theorem 5 [15]. *For a PILP in the form (1), and a given vector $v \in \mathbb{R}^m$, define the function F_v as*

$$\begin{aligned} F_v(d) = vd - \max \{ & (vA_{\mathcal{D}_v} - c_{\mathcal{D}_v})x \\ & | A_{\mathcal{D}_v}x \leq d, x \in \mathbb{Z}_+^{|\mathcal{D}_v|} \}, \end{aligned} \quad (25)$$

where $\mathcal{D}_v = \{j \in I : v\alpha^j > c_j\}$. Then, F_v is a feasible solution to the subadditive dual problem (11) and furthermore, if $b \in \Omega$ and $z(b) > -\infty$, there exists a $v \in \mathbb{R}^m$ such that $F_v(b) = z(b)$.

Klabjan [15] also introduced an algorithm that finds the optimal dual function utilizing a subadditive approach from Burdet and Johnson [16] together with a row generation approach that requires the enumeration of feasible solutions.

Lagrangian Relaxation

A mathematical program obtained by relaxing and subsequently penalizing the violation of a subset of the original constraints, called the *complicating constraints*, is a *Lagrangian relaxation* (Fisher [17]). Suppose that for a given $d \in \mathbb{R}^m$ the inequalities defined by matrix A and right-hand side d are partitioned into two subsets defined by matrices A^1 and A^2 and right-hand sides d^1 and d^2 . Furthermore, let $\mathcal{S}_{LD}(d^1) = \{x \in \mathbb{Z}_+^r \times \mathbb{R}_+^{n-r} : A^1x = d^1\}$. Then, for a given penalty multiplier $v \in \mathbb{R}^{m-l}$, the corresponding Lagrangian relaxation can be formulated as

$$L(d, v) = \min_{x \in \mathcal{S}_{LD}(d^1)} cx + v(d^2 - A^2x). \quad (26)$$

Assuming $z(0) = 0$ and that $x^*(d)$ is an optimal solution to the original MILP with right-hand side d , we have $L(d, v) \leq cx^*(d) + v(d^2 - A^2x^*(d)) = cx^*(d) = z(d) \forall v \in \mathbb{R}^{m-l}$. Thus, the Lagrangian function defined by

$$L_D(d) = \max \{L(d, v) : v \in V\}, \quad (27)$$

with $V \equiv \mathbb{R}^{m-l}$, is a feasible dual function in the sense that $L_D(d) \leq z(d) \forall d \in \Omega$. Observe that for a given $d \in \Omega$, $L(d, v)$ is a concave, piecewise-polyhedral function.

L_D above is a weak dual function in general, but Blair and Jeroslow [18] showed that it can be made strong for PILP problems by introducing a quadratic term.

Theorem 6 [18]. *For a PILP in the form (1), denote the quadratic Lagrangian dual function as*

$$L_D(d, v) = \max_{\rho \in \mathbb{R}_+} L(d, v, \rho), \quad (28)$$

with

$$L(d, v, \rho) = \min_{x \in \mathbb{Z}_+^n} \left\{ (c - vA)x + \rho \sum_{i=1}^m (A_i x - d_i)^2 + vd \right\}, \quad (29)$$

where $v \in \mathbb{R}^m$, $\rho \in \mathbb{R}_+$ and A_i is the i^{th} row of A . Then for a given $v \in \mathbb{R}^m$, $L_D(d, v) \leq z(d) \forall d \in \Omega$. Furthermore, if $b \in \Omega$ and $z(b) > -\infty$, then for any $v \in \mathbb{R}^m$, $L_D(b, v) = z(b)$.

Branch and Bound

Let us assume now that the MILP (1) has a finite optimum and has been solved to optimality by a branch and bound algorithm. Let T be the set of leaf nodes of the resulting search tree. To obtain a bound for the node $t \in T$, we solve the LP relaxation of the following problem:

$$\begin{aligned} z^t(b) = \min \quad & cx \\ \text{s.t.} \quad & Ax = b \\ & x \geq l^t \\ & -x \geq -u^t \\ & x \in \mathbb{Z}^r \times \mathbb{R}^{n-r}, \end{aligned} \quad (30)$$

where $u^t, l^t \in \mathbb{Z}_+^n$ are the branching bounds applied only to the integer variables.

For each feasibly pruned node $t \in T$, let $(v^t, \underline{v}^t, \bar{v}^t)$ be the corresponding solution to the dual of the LP relaxation that is used to obtain the bound that allowed the pruning of node t . Note that such a solution is always available if the LP relaxations are solved using a dual simplex algorithm. For each infeasibly pruned node $t \in T$, let $(v^t, \underline{v}^t, \bar{v}^t)$ be a corresponding dual feasible solution with $v^t b + \underline{v}^t l^t - \bar{v}^t u^t \geq z(b)$ that can be obtained from the dual solution of the parent of node t and a dual ray that makes the dual problem unbounded.

Theorem 7 [9]. *If $b \in \Omega$ and $z(b) > -\infty$, then the function*

$$F_{BC}(d) = \min_{t \in T} \{v^t d + \underline{v}^t l^t - \bar{v}^t u^t\} \quad (31)$$

is an optimal solution to the dual (5).

Note that it is also possible to consider the dual information revealed by the intermediate tree nodes. Schrage and Wolsey [13] give a recursive algorithm to evaluate a dual function that approximates the value function better by considering the relations between intermediate nodes and their offsprings.

Generating Functions

Lasserre [19,20] introduced a different method for constructing the value function of PILPs that utilizes generating functions. This methodology does not fit well into a traditional duality framework, but nevertheless gives some perspective about the role of basic feasible solutions of the LP relaxation in determining the optimal solution of a PILP.

Theorem 8 [21]. *For a PILP in the form (1) with $A \in \mathbb{Z}^{m \times n}$, define*

$$z(d, c) = \min_{x \in S(d)} cx, \quad (32)$$

and let the corresponding summation function be

$$\hat{z}(d, c) = \sum_{x \in S(d)} e^{cx} \forall d \in \mathbb{Z}^m. \quad (33)$$

Then the relationship between z and $\hat{z}$ is

$$\begin{aligned} e^{z(d, c)} &= \lim_{q \rightarrow -\infty} \hat{z}(d, qc)^{1/q} \quad \text{or, equivalently,} \\ z(d, c) &= \lim_{q \rightarrow -\infty} \frac{1}{q} \ln \hat{z}(d, qc). \end{aligned} \quad (34)$$

A closed form representation of $\hat{z}$ can be obtained by solving the two sided $\mathbb{Z}$ -transform $\hat{F} : \mathbb{C}^m \rightarrow \mathbb{C}$ defined by

$$\begin{aligned} \hat{F}(s, c) &= \sum_{d \in \mathbb{Z}^m} s^{-d} \hat{z}(d, c) \\ &= \prod_{j=1}^n \frac{1}{1 - e^{c_j} s^{-a^j}}, \end{aligned} \quad (35)$$

with $s^d = s_1^{d_1} \dots s_m^{d_m}$ for $d \in \mathbb{Z}^m$ and where the last equality is obtained by applying Barvinok's [22] short form equation for summation problems over the domain of

integral points. This equality is well defined if $|s^{a^j}| > e^{c_j}$, $j = 1, \dots, n$ and the function $\hat{z}$ is then obtained by solving the inverse problem

$$\begin{aligned} \hat{z}(d, c) &= \frac{1}{(2i\pi)^m} \int_{|s_1|=\gamma_1} \dots \\ &\times \int_{|s_m|=\gamma_m} \hat{F}(s, c) s^{d-1^m} ds, \end{aligned} \quad (36)$$

where γ is a vector satisfying $\gamma^{a^j} > e^{c_j}$, $j = 1, \dots, n$ and $1^m = (1, \dots, 1) \in \mathbb{R}^m$.

Although it is possible to solve (36) directly by Cauchy residue techniques, the complex poles make this difficult. One alternative is to apply Brion and Vergne's (see Lasserre [21] and Brion and Vergne [23] for details) lattice points counting formula in a polyhedron to get the reduced form, which, for each $d \in \mathbb{R}^m$, is composed of the optimal solution value of the LP relaxation and a correction term. The correction term is the minimum of the sum of the reduced costs of certain nonbasic variables over all basic feasible solutions, obtained by the degree sum of certain real-valued univariate polynomials. Another approach using generating functions is to apply Barvinok's [24] algorithm for counting lattice points in a polyhedron of fixed dimension to a specially constructed polyhedron that includes for any right-hand side the corresponding minimal test set (see De Loera *et al.* [25,26] for details).

CONCLUSION

Considering the fact that computing the value function for just a single right-hand side is an NP-hard optimization problem in general, computing the value function must necessarily be extremely difficult. The theory of duality, in turn, enables us to derive tractable methods for generating dual functions that approximate the value function and are at the core of a variety of MILP optimization algorithms including sensitivity analysis, warm starting, stochastic and multilevel programming algorithms.

It has so far been difficult to replicate for integer programming the functional and efficient implementations of dual methods we have become so accustomed to in the linear programming case. However, with recent advances in computing, an increased attention is being devoted to integer programming duality in the hope that new computational tools can contribute to more successful implementations.

INTRODUCTION

The past few decades have seen tremendous improvements in logistics processes. Logistics costs in the United States dropped from 16% of GDP in 1981 to below 9% in 2002 [1], signifying the efficiency gains. A large part of this trend can be attributed to the long line of academic and industrial research on logistics management that has emerged since World War II. From the 1990s onward, much of the research focus has been shifted to the broader area of supply chain management (SCM). In addition to the efficient flow and storage of materials studied in logistics, researchers are now dealing with a much wider range of business problems including the management of information, incentives to align conflicting interests, mitigation of risks, and the interfaces with different business functions such as marketing and finance. We have seen much research effort on identifying the best practices to manage and operate a network of facilities (e.g., factories, warehouses, retail stores), parts of which may be owned by different parties, to maximize long-term profitability. However, a necessary condition to ensure the successful implementation of these policies is the existence of a

well-designed facilities network as a backbone for all operations.

Traditionally, researchers and practitioners tackle the *logistics network design* problem using facility location models. Throughout the history of development of the location research field, the most important factor of consideration has been *distance*. All the classical location models, such as the median, center, and covering models, focus on the tradeoff between measures of distance and measures of budget. These correspond to the line-haul shipping and facility investment components of the logistics costs. For an excellent coverage of the field, the reader may refer to the texts by Daskin [2], Drezner [3] and Drezner and Hamacher [4].

In practice, however, the *supply chain* activities at the *tactical* and *operational* levels after a network of facilities is constructed often go far beyond the scope of shipping and investment costs. Classical location models, when applied to supply chain settings, tend to generate myopic solutions because they ignore the subtle effects of these SCM activities. For example, a distance-focused location model would suggest identical network designs for firms selling fashion items, machine spare parts, or grocery, as long as the transportation and facility investment costs are the same. This is clearly inconsistent with the wide range of SCM practices that have been developed to cater to different product natures. For example, spare parts supply chains typically operate under tight delivery time constraints, because of the destructive circumstances of late deliveries, such as shutting down of factories for assembly machines and delays of flights for aircrafts. To model the response and delivery lead times, one must pay attention to the inventory dynamics of the supply chain [5,6]. Because of these special considerations, supply chain design (SCD) models formulated for spare parts applications are usually not directly applicable to other settings, and vice versa.

The emerging stream of research on integrated supply chain design (ISCD) attempts to acknowledge this gap in the classical theory. Since network design decisions have a long-lasting impact on future costs and revenues, it is important to consider activities in the tactical and operational phases when making strategic decisions. This is the main idea behind the family of ISCD models. If tactical and operational costs incurred by future decisions such as holding inventory and distribution management are carefully estimated when making location decisions, it is more likely that the resulting supply chain will generate higher long-term profit. The reason is that some fundamental tradeoffs in supply chain design cannot be adequately reflected by classical location models that focus on distance–budget considerations. For example, the consideration of inventory holding costs alters the fundamental tradeoff between fixed and shipping costs in the classical uncapacitated facility location (UFL) model. Computational studies conducted by Shen *et al.* [7] suggest that, owing to economies of scale in inventory replenishment and risk pooling, it is optimal for a firm that holds inventory at a warehouse to locate fewer warehouses than suggested by the UFL model.

In this article, we illustrate the key ideas of ISCD modeling by reviewing several recent advances. We do not attempt to review the literature exhaustively. The interested reader may refer to Shen [8] for a more comprehensive survey. Owing to the wide coverage of the research stream, some important study areas are inevitably omitted. For example, the design of spare parts inventory networks [5,6,9] is one of the active research areas not being covered in this article. The remainder of this article is organized as follows. In the section titled “Basic Model”, we discuss the basic model upon which various ISCD models can be built. Then in sections titled “Model with Inventory Considerations,” “Multiple Sourcing,” and “Reliability and Robustness Issues”, we review several important models that have influenced the development of the research stream. Finally, in the section titled

“Future Research Directions”, we discuss some promising future research directions.

BASIC MODEL

Among the classical location models, the UFL model (also known as the UFL or the fixed charge model) is frequently used for SCD. It is even introduced in undergraduate textbooks [10] as a basic model for SCD. To formulate this model, we first introduce the following notations:

SETS

I = set of retailers

J = set of candidate warehouse locations

COST PARAMETERS

f_j = fixed (annualized) cost of opening a warehouse at location j

μ_i = demand volume at retailer i

d_{ij} = shipping cost per unit demand from location j to retailer i

DECISION VARIABLES

X_j = 1 if a warehouse is located at j , 0 otherwise;

Y_{ij} = 1 if demand at retailer i is assigned to warehouse at j , 0 otherwise.

Then the UFL model can be formulated as the following integer program:

$$(\text{UFL}) : \min \sum_{j \in J} f_j X_j + \sum_{i \in I} \sum_{j \in J} \mu_i d_{ij} Y_{ij} \quad (1)$$

subject to

$$\sum_{j \in J} Y_{ij} = 1, \text{ for each } i \in I \quad (2)$$

$$X_j \geq Y_{ij}, \text{ for each } i \in I, j \in J \quad (3)$$

$$X_j \in \{0, 1\}, \text{ for each } j \in J \quad (4)$$

$$Y_{ij} \in \{0, 1\}, \text{ for each } i \in I, j \in J. \quad (5)$$

In the above, the objective (1) is to minimize the sum of fixed location and variable shipping costs. The constraints (2) require that each retailer be assigned to one warehouse, and constraints (3) require that a warehouse be opened if it is used to serve any demand. As discussed in the section titled “Introduction”, the model focuses on the strategic tradeoff between fixed costs of opening warehouses and the distance, or shipping costs, from warehouses to retailers (i.e., customers). Note that our framework can also be used to model different type of facilities. For example, instead of warehouses and retailers, we may modify our model to study the location of factories that serve distribution centers.

To account for impacts of future SCM activities, it is natural to extend the UFL by adding terms that reflect the costs incurred in the tactical and operational phases. For example, we may use $G_j(\mathbf{Y})$ to denote the tactical and operational (except shipping) costs for a warehouse at site j , given demand assignments according to $\mathbf{Y}$.¹ The formulation now becomes

$$\begin{aligned} \min \sum_{j \in J} f_j X_j + \sum_{i \in I} \sum_{j \in J} \mu_i d_{ij} Y_{ij} \\ + \sum_{j \in J} G_j \left(\sum_{i \in I} \mu_i Y_{ij} \right) \end{aligned} \quad (6)$$

subject to Equations (2–5).

In the following sections, we discuss several representative models that fit the above general framework.

MODEL WITH INVENTORY CONSIDERATIONS

The UFL model captures the basic tradeoff between facility investment costs and shipping costs. However, this simple tradeoff fails to cover certain crucial issues in a

supply chain setting. In particular, tactical inventory management costs at warehouses exhibit economies of scale with respect to demand volume. In classical inventory theory [11], such economies of scale are achieved through economic ordering for cycle stock replenishments and risk pooling of safety stocks. In this section, we discuss a variant of model (6) that captures such impacts of inventory management on facility location decisions. The model was originally proposed by Shen *et al.* [7].

We begin by modifying and defining the following parameters:

DEMAND PARAMETERS

- μ_i = mean (daily) demand at retailer i
- σ_i^2 = variance of (daily) demand at retailer i
- α = desired probability of having no stock-outs during the lead time of a replenishment cycle
- z_α = standard normal deviate, where $P(Z \leq z_\alpha) = \alpha$
- L = order lead time at warehouse

COST PARAMETERS

- h_j = inventory holding cost at site j per unit per year
- F_j = fixed administrative and handling cost of placing an order at warehouse j
- g_j = fixed shipment cost per shipment from supplier to warehouse j
- $\bar{a}_j$ = variable cost per unit shipment from supplier to warehouse j
- χ = number of days in a year

In this model, we assume that retailers face independent, normally distributed demand. The goal is to decide the number and locations of warehouses, considering the resulting investment, shipment, and inventory costs. Inventory is controlled at each warehouse using a continuous review (r, Q) policy, subject to Type 1 service level requirements (α) . To simplify the ordering decisions, the cycle order quantities are determined by the economic order quantity (EOQ)

¹In this article, a letter in boldface represents the vector or matrix of variables denoted by the same letter. For example, $\mathbf{Y}$ represents the matrix with elements being the Y_{ij} 's.

based on the mean demand served by the warehouse.

Cycle Stock Costs

We first note that the daily expected demand going through warehouse j is given by $D_j = \sum_{i \in I} \mu_i Y_{ij}$. Suppose that the number of replenishments in a year at warehouse j is n_j . Then the average shipment size is $\chi D_j / n_j$ and the average inventory on-hand is approximately $\chi D_j / (2n_j)$. Each shipment from the supplier to warehouse j incurs a cost of $g_j + \bar{a}_j \chi D_j / n_j$, which consists of a fixed and a variable component. Then the annual working inventory cost at warehouse j is given by

$$F_j n_j + (g_j + \bar{a}_j \chi D_j / n_j) n_j + h_j \chi D_j / (2n_j).$$

We may observe that the expression above is similar in structure to the cost expression in the EOQ problem. Therefore, the optimal number of replenishments per year is given by

$$n_j^* = \sqrt{\frac{h_j \chi D_j}{2(F_j + g_j)}}.$$

Correspondingly, the annual working inventory cost associated with warehouse j is given by:

$$\sqrt{2h_j \chi D_j (F_j + g_j)} + \bar{a}_j \chi D_j.$$

Safety Stock Cost

We now formulate the safety stock cost for the model. The classical newsvendor model [12] suggests that the amount of safety stock needed to meet a Type-1 service level of α is given by z_α times the standard deviation of demand during lead time. Using our notation, the holding cost for the safety stock at warehouse j is then given by

$$h_j z_\alpha \sqrt{L \sum_{i \in I} \sigma_i^2 Y_{ij}}. \quad (7)$$

Complete Model Formulation

Adding the above cost expressions to a UFL-type formulation, we obtain the following

ISCD model:

$$\begin{aligned} \min \sum_{j \in J} & \left[f_j X_j + \sum_{i \in I} (d_{ij} + a_j) \chi \mu_i Y_{ij} + \sqrt{2h_j (F_j + g_j)} \right. \\ & \times \left. \sqrt{\sum_{i \in I} \chi \mu_i Y_{ij} + h_j z_\alpha \sqrt{\sum_{i \in I} L \sigma_i^2 Y_{ij}}} \right] \\ = \sum_{j \in J} & \left[f_j X_j + \sum_{i \in I} \hat{d}_{ij} Y_{ij} + K_j \sqrt{\sum_{i \in I} \mu_i Y_{ij}} \right. \\ & \left. + \eta_j \sqrt{\sum_{i \in I} \sigma_i^2 Y_{ij}} \right] \end{aligned} \quad (8)$$

subject to Equations (2–5)
where

$$\begin{aligned} \hat{d}_{ij} &= (d_{ij} + a_j) \chi \mu_i \\ K_j &= \sqrt{2h_j (F_j + g_j)} \\ \eta_j &= h_j z_\alpha \sqrt{L}. \end{aligned}$$

Solution Approaches

The above model has been studied by Shen *et al.* [7] and Daskin *et al.* [13]. One interesting property uncovered was that unlike the traditional UFL model, in which it is always optimal to assign a retailer to the open warehouse that incurs the lowest shipping cost, it is sometimes optimal to assign demand to more remote warehouses in the new model in order to achieve economies of scale by inventory sharing. In the case where the sets of retailer and candidate warehouse locations are the same ($I = J$), it is even possible that a warehouse does not even serve a retailer at the same location. These pathological situations, however, do not occur when the mean–variance ratio of demand is the same for all retailers (i.e., $\sigma_i / \mu_i = \gamma, \forall i \in I$). This condition holds in many practical settings. For example, if demands follow Poisson distributions, the mean–variance ratio will be equal to 1 for all retailers. Both papers develop algorithms based on this assumption, which allows the objective function to

be rewritten as

$$\min \sum_{j \in J} \left[f_j X_j + \sum_{i \in I} \hat{d}_{ij} Y_{ij} + \hat{K}_{ij} \sqrt{\sum_{i \in I} \mu_i Y_{ij}} \right],$$

where $\hat{K}_j = K_j + q_j \sqrt{\gamma}$.

The algorithms developed in the two papers are closely related. Shen *et al.* [7] utilize a column generation approach, which involves reformulating the problem as a set-covering problem, solving restrictions of the problem with only a subset of variables, and successively adding variables that reduce the cost to improve the formulation. Daskin *et al.* [13], on the other hand, improve the computational results by using a Lagrangian relaxation procedure by relaxing constraints (2). For a tutorial on the Lagrangian relaxation approach, the interested reader may refer to Fisher [14]. In both algorithms, a subproblem of the following form (or pricing problem) has to be solved in each iteration, for each candidate site $j \in J$:

$$\min_{Z \in \{0,1\}^{|I|}} \sum_{i \in I} b_i Y_i + \sqrt{\sum_{i \in I} c_i Y_i}, \quad (9)$$

where $c_i \geq 0$, but $b_i < 0$. A lower order polynomial time procedure, developed by Shen *et al.*, was utilized in both algorithms to solve the above subproblem. The procedure is based on the special structure of the above subproblem. The first term in the objective function is linearly decreasing in Y_i , while the second term is concave increasing in Y_i . Intuitively, this structure of this subproblem is somewhat related to that of the knapsack problem, in the sense that one wants to activate variables (set Y_i to 1) to improve the cost linearly, while limited by a penalty that works in a similar fashion as the capacity constraint in the knapsack problem. On the basis of this observation, Shen *et al.* prove that after sorting the i 's by the b_i/c_i ratio, it is possible to identify an optimal solution by checking at most $|I|$ candidate solutions. Therefore, the complexity of solving the subproblem for each $j \in J$ is $O(|I| \log |I|)$ and that of solving all $|J|$ subproblems in one iteration of column generation or Lagrangian relaxation is $O(|I||J| \log |I|)$.

To solve the problem without the restriction that all retailers have equal mean-variance ratio for demand, Shu *et al.* [15] build on the Shen *et al.* column generation algorithm. The resulting pricing problem is similar to Equation (9), but contains one more square root term in the objective function. Exploiting the fact that the subproblem is equivalent to minimizing a submodular set function together with other structural properties, they develop an efficient algorithm that solves the subproblem in $O(|I|^2 \log |I|)$ time. Solving all $|J|$ subproblems in one iteration thus has complexity of $O(|I|^2 |J| \log |I|)$.

Recently, Berenguer *et al.* [16] studied an ISCD model with unreliable supply and transportation. Their solution approach involves reformulating ISCD models as mixed-integer second-order cone programs (MISOCPs), the continuous relaxations of which can be efficiently solved with conic programming solvers in polynomial time. In addition, several classes of cutting planes [17–19] can be used to exploit the special structure of MISOCPs and speed up the branch-and-bound procedure. It is interesting to note that problem (6) can also be written as the following MISOCP:

$$\min \sum_{j \in J} \left[f_j X_j + \sum_{i \in I} \hat{d}_{ij} Y_{ij} + K_j V_j + q W_j \right],$$

subject to

$$V_j \geq \sqrt{\sum_{i \in I} \mu_i Y_{ij}^2}, \quad (10)$$

$$W_j \geq \sqrt{\sum_{i \in I} \sigma_i^2 Y_{ij}^2}, \quad (11)$$

plus Equations (2–5).

Inequalities (10) and (11) are second-order conic constraints. Note that the two formulations are equivalent because $Y_{ij} = Y_{ij}^2$ for $Y_{ij} \in \{0, 1\}$.

Key Insights

One might question how much this more complex model improves over the relatively simpler UFL. Computational comparisons

between these models show that the solution obtained by solving the UFL always overestimates the number of facilities needed. This is due to the fact that the UFL does not account for the economies of scale in inventory costs. From the computational experiments conducted by Shen *et al.* [7], supply chain networks based on UFL solutions, on average, incur about 7% extra cost compared to the optimal solution obtained by solving the model discussed above. This suggests the potential benefits of building more sophisticated ISCD models to capture the underlying dynamics that are not accounted for in the classical models.

Extensions

Impact of Capacity Constraints. In practical settings, warehouses typically have limited capacity. The traditional way to model warehouse capacity is to constrain the maximum demand volume that can be assigned to a facility, as is done in the classical capacitated facility location (CFL) problem. However, in a supply chain setting, capacity restrictions at a warehouse depend more on the maximum inventory level than on (average) demand volume. On the basis of this observation, Ozsen *et al.* [20] formulate a capacitated version of model (6). Their capacity constraint is defined on the basis of the maximum level of inventory kept at the warehouse. This constraint allows an additional layer of freedom in demand assignment, because instead of strictly prohibiting the assignment of high demand volumes to warehouses, this model allows warehouses handling high demand volumes to lower peak inventory levels by ordering frequently in small lots. As a result, the model captures the tradeoff between locating more warehouses to ensure efficient capacity utilization versus ordering smaller lots to operate under capacity.

Recall that inventory is managed at each warehouse using an (r, Q) policy. Note that the absolute maximum inventory level at a warehouse is reached in the following (unlikely) situation: after a reorder request, the demand during the lead time is zero. Therefore, the maximum inventory level is equal to the reorder point plus the order quantity. Denoting the capacity and cycle

order quantity at warehouse j by C_j and Q_j , respectively, the capacity constraint can be written as

$$Q_j + z_\alpha \sqrt{L \sum_{i \in I} \sigma_i^2 Y_{ij}} + \sum_{i \in I} L \mu_i Y_{ij} \leq C_j. \quad (12)$$

Recall that for (r, Q) inventory systems, the reorder point is equal to the safety stock plus expected lead time demand. These are equal to the second and third terms on the left hand side of Equation (12), respectively.

To solve this problem, Ozsen *et al.* extend the Lagrangian relaxation algorithm of Daskin *et al.* [13]. Their subproblem has a similar form to Equation (9), with the square root function replaced by a function that is neither convex nor concave. They prove that each of the new subproblems can be solved with the sorting algorithm [7] with an additional subroutine to search for roots in at most $|I|$ subintervals within a line segment. They then modify the Lagrangian relaxation algorithm of Daskin *et al.* accordingly to solve the capacitated SCD problem.

Impact of Operational Shipment Consolidation. In daily logistics operations where demand points have relatively small demand volumes, it is possible to lower delivery cost by consolidating shipments using milk runs, that is, delivering to multiple demand points with the same vehicle on the same route. Therefore, when retailers have low-demand volumes and/or place frequent replenishment requests, there is a possibility to achieve greater economies of scale using vehicle routing. Recall that in all the previous models, it is assumed that shipping costs from warehouses to retailers are linear in demand volumes. To capture the impact of such operational economies of scale on the optimal network configuration, it is necessary to further extend the objective function to include operational vehicle routing costs.

Like most facility location problems, the vehicle routing problem (VRP) is NP-hard. Owing to the high complexities of both problems, it is not practical to directly combine a vehicle routing problem and an ISCD problem. Fortunately, we are mainly concerned about the strategic design aspects rather

than the operational details at this stage. Therefore, it suffices to approximate the operational delivery costs by some tractable functions of demand volumes. The concept of continuous approximation in logistics analysis (see Daganzo [21] for a thorough treatment of the subject) is then very helpful. By using a concise summary of problem characteristics (e.g., the total demand volume and the number of retailers), it is possible to obtain simple tractable approximations for analysis or optimization. One such approximation for the optimal VRP length (V_j), that is, total distance traveled by all vehicles needed to visit all retailers once, is given by Haimovich and Rinnooy Kan [22]:

$$V_j \approx \frac{2}{\kappa} \sum_{i=1}^m d_{ij} \mu_i + \left(1 - \frac{1}{\kappa}\right) \psi_j. \quad (13)$$

In the above equation, m is the number of retailers visited, κ is the capacity of a vehicle, and ψ_j can be interpreted as a local detour distance. Intuitively, the first term gives the total distance traveled by all vehicles from the depot to the respective local neighborhoods and back. The second term (the detour lengths) represents the distance traveled within the respective local neighborhoods to visit all local retailers. Furthermore, based on the results by Daganzo [23], Shen and Qi [24] show that if N retailers are uniformly distributed in a region of area A , m of which are visited and m is large (> 100), then the expected detour length ψ_j can be approximated by

$$\psi_j \approx \rho m \sqrt{\frac{A}{N}}. \quad (14)$$

In the above, ρ is a constant that equals 0.75 for the Euclidean metric. Combining Equations (13) and (14), the VRP cost can then be approximated by

$$V_j \approx \frac{2}{\kappa} \sum_{i=1}^m d_{ij} \mu_i + \left(1 - \frac{1}{\kappa}\right) \rho m \sqrt{\frac{A}{N}}. \quad (15)$$

Shen and Qi assume that there is a dedicated truck in each warehouse that delivers to the retailers every period according to a certain route, and that the transportation

cost related to this route is an increasing and concave function $R_j(T_j)$ in the distance traveled, under reasonable conditions (e.g., driver does not have to work overtime). Then, the new ISCD problem incorporating strategic location, tactical inventory control, and operational vehicle routing elements can be formulated as

$$\min \sum_{j \in J} \left[f_j X_j + \sum_{i \in I} \hat{d}_{ij} Y_{ij} + \hat{K}_{ij} \sqrt{\sum_{i \in I} \mu_i Y_{ij}} + R_j \left(\sum_{i \in I} \hat{b}_{ij} Y_{ij} \right) \right],$$

where $\hat{b}_{ij} = 2\mu_i d_{ij}/\kappa + \chi(1 - 1/\kappa)\rho\sqrt{\frac{A}{N}} \geq 0$.

Shen and Qi further develop a Lagrangian relaxation algorithm by exploiting the structure of a subproblem that is similar to Equation (9), but involves three concave terms. They generalize the procedure proposed by Shu *et al.* [15] to solve the subproblem in $O(|I|^2 \log |I|)$ time.

MULTIPLE SOURCING

One key assumption made in the models discussed in the section titled “Model with Inventory Considerations” is that all retailers use single sourcing, that is, receive shipments from only one warehouse. In practical settings, such an arrangement may reduce operational complexity, because demand allocation rules are relatively simple. However, this simplicity does not come without a cost. First, the single sourcing requirement restricts efficient utilization of capacity. Second, a single sourcing arrangement is not responsive to dynamic changes of demand. In this section, we discuss models that address these two issues, respectively. Both models allow multiple sourcing arrangements, in which each retailer can receive shipments from multiple warehouses in such a way that minimizes cost.

Enhancing Capacity Management by Static Multiple Sourcing

In classical UFL problems such as the UFL and P-median problems, there exist single

sourcing solutions that are optimal even if multiple sourcing is allowed. However, when the facilities have capacity limits, multiple sourcing allows splitting of a retailer's demand to fit within the assigned warehouses' capacity limits and therefore achieves lower costs. In the ISCD setting, we have discussed in the section titled "Key Insights" how warehouse capacity can be defined on the basis of storage space for inventory. We now discuss the multiple sourcing version of the same model, as developed by Ozsen *et al.* [25].

The multiple sourcing arrangements allowed in this model are static, meaning that a retailer's demand has to be split among multiple warehouses in fixed proportions, which are to be determined endogenously together with the location decisions. For example, at the SCD stage, it is determined that a retailer will place half of its orders at warehouse 1 and the other half at warehouse 2, and will not adjust this ratio over time. The reason for maintaining such consistent sourcing ratios is to efficiently allocate demand to warehouses such that capacities can be utilized at a low cost manner. As done in the classical CFL, static multiple sourcing can be modeled by allowing the demand assignment variables (Y_{ij}) to be fractional instead of binary. Therefore, the model is identical to Equation (6), except that constraints (5) are replaced by

$$0 \leq Y_{ij} \leq 1, \text{ for each } i \in I, j \in J. \quad (16)$$

The solution algorithm is similar to the one designed for the single-sourcing version. The authors show that, despite the freedom to split demands, it is optimal to do only a limited degree of splitting. For example, there exists an optimal solution if the number of multisourced retailers is smaller than the number of warehouses open.

Responding to Demand Fluctuations by Dynamic Sourcing

The static multiple sourcing arrangement discussed in the previous section makes demand assignment a strategic decision that cannot respond to fluctuations of demand and other problem parameters. As SCD decisions usually govern long-term supply

chain performance and accurate forecasts for future market conditions are seldom available, it is important to insert certain degrees of flexibility in the network configuration. One possible example of flexibility is to use multiple sourcing, and allow sourcing proportions to be determined subject to realization of the initially unknown parameters, such as demand volumes. Mak and Shen [26] formulate a two-stage ISCD model to study the cost-benefit tradeoff for such flexibility.

In the first (*design*) stage, the network structure, that is, location of DCs and the allocation of retailers to DCs, is to be determined. Then in the second (*management*) stage, the inventory and shipment decisions are made for a number of periods given the network structure determined in the design stage. We first introduce the following additional notations:

Cost and Other Parameters

- c_{ij} = fixed (annualized) cost of creating an arc connecting DC j and retailer i
- T = number of periods in management stage
- D^t = demand vector in period t , following a known probability distribution

Decision Variables

- $Z_{ij} = 1$ if we build an arc between DC j and retailer i , 0 otherwise.

The two-stage stochastic programming problem can be formulated as follows:

$$\min \sum_{j \in J} f_j X_j + \sum_{i \in I} \sum_{j \in J} c_{ij} Z_{ij} + v(\mathbf{X}, \mathbf{Z}, D^1, \dots, D^T) \quad (17)$$

subject to

$$\begin{aligned} \sum_{j \in J} Z_{ij} &\geq 1, \text{ for each } i \in I \\ X_j &\geq Z_{ij}, \text{ for each } i \in I, j \in J \\ X_j &\in \{0, 1\}, \text{ for each } j \in J \\ Z_{ij} &\in \{0, 1\}, \text{ for each } i \in I, j \in J. \end{aligned}$$

In the above formulation, $v(\cdot)$ is defined to be the expected recourse function, which includes the inventory, shipping, and shortage costs in the management stage. Mak and Shen [27] provide the detailed formulation and prove various properties, including the optimality of using stationary base stock policies at the warehouses. They provide an efficient algorithm to obtain high-quality solutions to the problem.

From computational experiments, Mak and Shen obtain the following insights. First, adding sourcing flexibility can dramatically enhance the network's ability to mitigate demand risks. Second, by adding a small degree of flexibility, it is possible to achieve most of the benefits of complete flexibility (i.e., any retailer can receive shipments from any warehouse). This finding echoes the classical results in process flexibility [28,29]. Third, the optimal degree of flexibility increases with demand variability and decreases with demand correlation across retailers.

RELIABILITY AND ROBUSTNESS ISSUES

SCD involves long-term decisions that are difficult to reverse. Therefore, the network that we design today will be subject to changes in the business environment in the future years and even decades. Unfortunately, it is well known as one of the fundamental principles of forecasting that the longer the forecast horizon, the less accurate the forecast will be [30, Chapter 2]. Unlike operational decisions such as machine scheduling, strategic network design decisions have to be made on the basis of imprecise long-term forecasts of input parameters such as fuel cost and demand rate. Therefore, it is in the best interest of the organization to design a robust network that performs reasonably well under any possible realization of the uncertain parameters for which only rough estimates are available.

There has been a significant amount of work on facility location under uncertainty. Snyder [31] provides an excellent review of the subject. However, these models, just like the classical location models, do not

account for the implications of tactical and operational activities of the system. On the other hand, there has been relatively little work in the ISCD stream that involves uncertainty issues. In the section titled "Parameter Uncertainty and Scenario Analysis", we first discuss an ISCD model that takes the uncertainty of input parameters into account. Then, we move on to models that handle two important risk factors, namely, the randomness of supply yield and potential disruptions of facilities, in sections titled "Unreliable Supply" and "Dynamic Sourcing under Disruptions," respectively. It is worth noting that the three categories of uncertainty models are closely related, yet distinct. Parameter uncertainty models (section titled "Parameter Uncertainty and Scenario Analysis") assume that certain input parameters follow certain probability distributions (or lie within certain support intervals), and optimize either the expected or the worst-case performance accordingly. The other two categories focus on the unreliability of supply. Random yield models (section titled "Unreliable Supply") assume that the amount of products received by a retailer or a customer is a random proportion of the ordered amount. Disruption models (section titled "Dynamic Sourcing under Disruptions") assume that, with a certain probability, a warehouse cannot function (i.e., is disrupted) and supplies zero amount to retailers that it is supposed to serve. It is possible to model unreliable supply using parameter uncertainty, by assuming that the supply level is one of the uncertain parameters. It is also possible to model disruptions with random yield, by assuming that the yield follows a Bernoulli (all-or-nothing) distribution. However, these approaches are not desirable, because they do not take into account specific characteristics of the respective problems. For example, strategies such as keeping safety stocks are effective measures to adapt to yield uncertainty, while parameter uncertainty models do not take this into account. On the other hand, as has been pointed out by Chopra *et al.* [32], recurrent supply risk (random yield) and disruption risks are different fundamentally

in terms of mitigation strategies and ought not be confused.

Parameter Uncertainty and Scenario Analysis

Addressing the issue that it is impossible to accurately predict the future business environment at the design stage, Snyder *et al.* [33] formulate a scenario-based model. Scenario-based optimization is a key idea that is widely used in stochastic programming [34], and is consistent with scenario-based planning frequently adopted by managers. With some parameters (e.g., demand volume) being uncertain at the time of design, we may define a finite set of possible realizations or scenarios (denoted by S), and assign a probability or weight ($q_s, s \in S$) to each of them. The objective is to minimize the expected cost over this distribution of scenarios. In this model, the facility location decisions are strategic decisions that must be made before the scenario realization is observed, based on the probability distribution discussed above. Then, when the supply chain network is in operation and the scenario realization is observed, the manager may adjust the retailer-warehouse assignments to minimize cost.

There are two possible interpretations for this framework. First, we may assume that one of the set of parameter scenarios will be realized, and the parameter values remain as they are from then on. Second, we may assume that the parameters are dynamically changing over time, and the long-term proportion of time that each scenario s is realized is equal to the probability q_s . To formulate this model, we redefine the following uncertain parameters and recourse decision variables to make them dependent on the realized scenario:

Parameters

- μ_{is} = mean daily demand at retailer i under scenario s
- σ_{is}^2 = variance of daily demand at retailer i under scenario s
- d_{ijs} = shipping cost per unit from warehouse j to retailer i under scenario s

Decision Variables

$Y_{ijs} = 1$ if demand at retailer i is assigned to warehouse at j when scenario s is realized, 0 otherwise.

Then the scenario-based problem can be formulated as follows:

$$\sum_{s \in S} q_s \sum_{j \in J} \left[f_j X_j + \sum_{i \in I} \hat{d}_{ijs} Y_{ijs} + K_j \sqrt{\sum_{i \in I} \mu_{is} Y_{ijs}} + \eta_j \sqrt{\sum_{i \in I} \sigma_{is}^2 Y_{ijs}} \right]$$

subject to

$$\begin{aligned} \sum_{j \in J} Y_{ijs} &= 1, \text{ for each } i \in I, s \in S; \\ X_j &\geq Y_{ijs}, \text{ for each } i \in I, j \in J, s \in S; \\ X_j &\in \{0, 1\}, \text{ for each } j \in J; \\ Y_{ijs} &\in \{0, 1\}, \text{ for each } i \in I, j \in J, s \in S; \end{aligned}$$

where $\hat{d}_{ijs} = (d_{ijs} + a_j) \chi \mu_{is}$.

Snyder *et al.* [33] devise a Lagrangian relaxation algorithm to solve the problem. The subproblem at each iteration turns out to be identical to the one encountered in solving the model in the section titled “Model with Inventory Considerations”. Their computational results show that the solution obtained by solving the scenario-based model is often very different from the ones obtained by solving the problem assuming no uncertainty. The latter solutions typically perform poorly in the long run in the presence of parameter uncertainty.

Independently, Shen [35] develops a similar model with a different interpretation. Instead of being scenarios of realizations of uncertainty, the set S represents the collection of different commodities sold by the firm in Shen’s model. These commodities have separate demand volumes and inventories, but are handled at the same warehouses. Comparing the two models, Shen’s is slightly more general because it uses a general increasing and concave inventory cost term, which includes Snyder *et al.*’s EOQ-based inventory cost function as a special case.

Unreliable Supply

We have seen that firms that were not prepared to respond to unreliable supplies, such as Ericsson in the 2000 Albuquerque fire, suffered huge losses and lost their market leadership. As the backbone of all supply chain operations, the supply chain network must be designed by taking supply risk factors into account to ensure ample supply.

Qi and Shen [36] study a problem in which supply is not perfectly reliable. They consider a multiple-period problem in which the amount that a retailer receives from its assigned warehouse is a random fraction (the reliability coefficient) of the original order quantity. This assumption is also known as *random yield* [37] in the production control literature. Besides facility location costs, working inventory costs, safety stock costs, and shipping costs that have been considered in the section titled “Model with Inventory Considerations”, the Qi and Shen model also takes into account the penalty costs of not meeting the retailers’ demand in full. We begin by introducing the following additional notations:

Parameters

- c = purchasing price per unit of product from supplier
- τ = number of periods per year
- R_j = reliability coefficient associated with facility j
- p_i = retailer price per unit of product at retailer i
- π_i = penalty (goodwill) cost for missing each unit of demand at retailer i
- u_i = salvage value of product at retailer i

Decision Variables

- ω_{ij} = quantity that retailer i orders from facility j in each period (assumed to be constant over time).

Utilizing the result on inventory control under unreliable supply provided by Dada *et al.* [38], they formulate a model of the following structure:

$$\begin{aligned} \max - \sum_{j \in J} \left[f_j X_j + c \tau \sum_{i \in I} \omega_{ij} + a_j \tau \sum_{i \in I} \omega_{ij} \right. \\ \left. + K_j \sqrt{\sum_{i \in I} \omega_{ij}} \right] + \tau \sum_{i \in I} \Upsilon_i(\mathbf{Q}) \end{aligned}$$

subject to

$$\begin{aligned} 1 - e^{-\beta \omega_{ij}} &\leq X_j, \text{ for each } i \in I, j \in J \\ \omega_{ij} &\geq 0, \text{ for each } i \in I, j \in J \\ X_j &\in \{0, 1\}. \end{aligned} \quad (18)$$

The objective is to maximize the expected annual profit of the entire system. The first two terms represent the fixed location costs and the purchase costs of products. The third and fourth terms represent the sum of inventory and delivery costs. Finally, the last term represents the difference between sales revenues of the retailers and inventory costs. The exact form is derived by Dada *et al.* [38] as follows:

$$\begin{aligned} \Upsilon_i(\mathbf{Q}) = E \left\{ p_i D_i + u_i \left[\sum_{j \in J} R_j \omega_{ij} - D_i \right]^+ \right. \\ \left. - (p_i + \pi_i) \left[D_i - \sum_{j \in J} R_j \omega_{ij} \right]^+ \right. \\ \left. - \sum_{j \in J} d_{ij} R_j \omega_{ij} \right\}. \end{aligned}$$

The constraints (18) ensure that retailers cannot place orders at warehouses that are not opened. In devising an efficient Lagrangian relaxation algorithm to solve the problem, Qi and Shen found that a constraint of this form is more effective than one of the form $MX_j \geq \omega_{ij}$.

Dynamic Sourcing under Disruptions

Following a series of catastrophic events over the past decade, including the September 11 terrorist attack and the strike of Hurricane Katrina, researchers and practitioners have put increasingly more emphasis on ensuring the reliability of supply chain networks.

Owing to the practical significance, strategies to deal with reliable supply have become a key issue in supply chain research. Most of the existing works focus on inventory control [39] and risk mitigation and contingency planning [40,41]. Mitigation strategies are those in which the firm takes action in advance and incurs a cost to prepare for uncertainty. Holding safety stock is an example of a mitigation strategy to adapt to uncertain demand. In contrast, contingency strategies are those in which the firm takes action after some event occurs. For example, emergency inventory transshipment during stock-outs can be regarded as a contingency strategy to adapt to demand uncertainty.

There is also a significant stream of research on facility location under disruption risks. Snyder and Daskin [42] study the optimal network configuration that minimizes a weighted average of regular shipping costs and the expected failure costs in case of disruptions, assuming that probabilities of disruptions at all candidate facility locations are equal. The equal-probability assumption is relaxed in related works by Berman *et al.* [43], who focus on asymptotic properties of the problem; Zhan *et al.* [44], who propose and solve a mixed-integer nonlinear programming version of the problem; Shen *et al.* [45], who formulate and solve a two-stage stochastic program and then a nonlinear integer program and provide an approximation algorithm with constant worst case bound for the special case where the probability that a facility fails is a constant; and Cui *et al.* [46], who provide a linear formulation and study qualitative insights by using a continuous approximation model. Lim *et al.* [47] study a closely related problem in which there is an option to locate disruption-proof, but more expensive, facilities. Despite the contributions of this stream of work, these works do not consider operational and tactical level decisions.

In one of the very few works on ISCD models under disruption risks, Mak and Shen [26] extend the model outlined in the section titled “Responding to Demand Fluctuations by Dynamic Sourcing” to study the impact of

warehouse disruptions in networks with and without the flexibility of dynamic sourcing. It is interesting to see that the dynamic multiple sourcing arrangement discussed in the section titled “Responding to Demand Fluctuations by Dynamic Sourcing” fits the definition of contingency under demand fluctuations. In fact, such an arrangement can also help limiting disruption risks, by dynamically adjusting the demand allocation proportions among the working facilities. The key insight behind their model is the following. Economies of scale in inventory replenishment and risk pooling of demand encourage the location of fewer warehouses, each handling a larger demand volume, as suggested in the section titled “Key Insights”. On the other hand, the risk of disruptions makes risk diversification, by locating more facilities, each handling a smaller demand volume—a desirable strategy. These two effects go against each other and it is difficult to find a balance. However, dynamic sourcing enhances inventory sharing across multiple locations (as suggested by the study covered in the section titled “Responding to Demand Fluctuations by Dynamic Sourcing”). Therefore, it is possible to achieve risk diversification by locating a large number of warehouses, while still achieving risk-pooling benefits using dynamic sourcing. From computational experiments, Mak and Shen show that dynamic sourcing is very effective in limiting losses incurred by facility disruptions. Furthermore, only small degrees of flexibility are needed to hedge against high disruption risks.

FUTURE RESEARCH DIRECTIONS

Interface with Marketing Strategies

Traditionally, logistics and marketing are treated as two separate business functions. Past research has treated the two areas independently. However, one can easily observe the close link between the two: logistics treats demand as given, and optimizes the supply process; marketing treats the supply process as given, and manages demand to maximize revenue. It is clear that decisions in

one function can greatly impact the performance in the other. In fact, some companies that manage to jointly formulate strategies considering both facets fare extremely well. For example, Zara allows frequent stock-outs of its products on purpose to induce consumers to purchase early and manages a supply chain network with redundant capacity to respond quickly to demand changes [48]. In this case, managing the two functions separately would have prohibited such success.

Not until recently has research on the interface between marketing and operations emerged. Some examples of active research areas include rationing and pricing strategies in the presence of strategic consumers [49–51], and the coordination of pricing and inventory decisions [52]. There are thus many promising research questions that fall within the context of retail network design that remain unanswered. For example, how does network design enable or prohibit effective market segmentations based on factors such as geographical location, pricing, product availability, and quality of service? Many of these factors, together with logistics operations such as inventory control and distribution planning, carry implications on the optimal network configuration. It will be a challenge to model and analyze the subtle relationships between these activities and the resulting implications on the optimal network configuration.

It is also important to study the impact of competition. Research on this topic would help us better understand some interesting phenomena such as the cluster entry strategy of 7-Eleven Japan of opening 50–60 stores at a time when entering new markets where competition exists [53]. Much of the existing research on competitive facility location (see Drezner [3] for a comprehensive review) focuses on capturing consumers from competitors by geographical proximity, capacity, and exogenous factors such as brand name. However, in supply chain settings, firms compete on many other factors, such as product offering and availability, logistics services, and even loyalty programs. Some of these factors have subtle implications on the strategic design

of the retail network, while some others may not. To synchronize the firm's marketing and logistics strategies with the network design decisions, one ought to investigate the potential impacts of these marketing and operation activities and carefully select the most important ones to be endogenized in the design model.

Designing Effective Implementation Mechanisms

The research directions previously outlined make the assumption that all design and operation decisions are made by a single manager with the goal of maximizing total supply chain profit. However, horizontal (e.g., an alliance of retailers) and vertical (e.g., a supply chain consisting of a retailer, distributor, and manufacturer) cooperation is common in modern supply chains. In such settings, there are multiple distinct parties with possibly conflicting interests. In an attempt to maximize the total supply chain profit, it is necessary to provide incentives such that all parties commit to a centralized solution. The centralized optimal solution is often impossible to implement, but it is usually possible to coordinate a solution in which every party can benefit compared to the case where decisions are completely centralized.

There exists a stream of research on incentives to induce inventory sharing [54]. However, there has been very limited research on cooperative SCD. The existing research on cooperative facility games [55] mostly deals with simple location problems such as the UFL and set-covering problems. Moreover, the focus of such research is mainly on algorithmic aspects such as computing equilibrium points, rather than obtaining managerial insights on how to implement such mechanisms in practice.

INTRODUCTION

In general, interior point methods (IPMs) refer to a special class of optimization algorithms for solving classes of linear and nonlinear programming problems. As indicated by their names, IPMs usually move in the interior of the feasible region of the underlying optimization problem and try to find an optimal solution by following a particular path that converges to the solution set of the corresponding optimization problem.

The study of IPMs can be dated back to the mid-1950s when Frisch [1,2] proposed the logarithmic barrier method for linear programming (LP). Similar ideas were also used by Fiacco and McCormick in Fiacco [3] and Fiacco and McCormick [4] to transfer constrained optimization problems into parameterized unconstrained problems by using penalty or barrier terms. The name of interior point methods first appeared in Fiacco and McCormick [4] where the relationships between minimizers of the barrier and penalty function and solutions of the original constrained problems were discussed in detail. However, despite the good features of barrier methods, Lootsma [5] and Murray [6] observed independently in the late 1960s that the Hessian of a barrier function becomes increasingly ill-conditioned as the solution is approached and is singular in the limit. Discouraged by

this serious drawback of barrier methods, many optimization experts around that time turned their interest to other methods such as augmented Lagrangian and sequential quadratic programming (SQP) methods [7–10] that seemed to be more efficient in practice without having ill-conditioning.

The modern era of IPMs dates back to 1984 when Karmarkar [11] announced his seminal work on a polynomial-time algorithm for linear programming that is efficient both in theory and practice. Since then, many variants of IPMs for linear and nonlinear optimization problems subject to certain constraints, including the primal, the dual, and the primal–dual IPMs, have been proposed and analyzed; for more details we refer to Alizadeh and Goldfarb [12], Nesterov and Nemirovski [13], Terlaky [14], Vandenberghe and Boyd [15], Wolkowicz *et al.* [16], Wright [17], and Ye [18] and the references therein.

A GENERIC FRAMEWORK OF PRIMAL–DUAL IPMS

In this survey, we focus only on the primal–dual framework, which is the most widely used one both in theoretical analysis [19–21] and practical implementation [22–24]. To start with, we consider NLPs in the following form:

$$\begin{aligned} \min_{x \in R^n} f(x) \\ c_i(x) = 0 \quad i \in \mathcal{E}, \\ c_i(x) \geq 0 \quad i \in \mathcal{I}, \end{aligned} \quad (1)$$

where f and $c_i(x)$'s are twice-continuously differentiable functions from R^n to R . By introducing the slack vector s we write Equation (1) as

$$\begin{aligned} \min_{x \in R^n} f(x) \\ c_i(x) = 0 \quad i \in \mathcal{E}, \\ c_i(x) - s_i = 0 \quad i \in \mathcal{I}, \\ s \geq 0. \end{aligned} \quad (2)$$

The Lagrangian function associated with this problem is

$$L(x, s, \lambda) = f(x) + \lambda_{\mathcal{E}}^T c_{\mathcal{E}}(x) - \lambda_{\mathcal{I}}^T (c_{\mathcal{I}}(x) - s), \quad (3)$$

where $\lambda_{\mathcal{E}}, \lambda_{\mathcal{I}}$ are Lagrange multipliers. The Karush-Kuhn-Tucker (KKT) conditions associated with Equation (2) can be written as

$$\begin{aligned} \nabla_x L(x, s, \lambda) &= 0, \\ c_i(x) &= 0 \quad i \in \mathcal{E}, \\ c_i(x) - s_i &= 0 \quad i \in \mathcal{I}, \\ S \Lambda_{\mathcal{I}} e &= 0, \\ s, \lambda_{\mathcal{I}} &\geq 0, \end{aligned} \quad (4)$$

where $S = \text{diag}(s)$ and $\Lambda_{\mathcal{I}} = \text{diag}(\lambda_{\mathcal{I}})$. Let us consider the following barrier problem for Equation (2):

$$\begin{aligned} \min_{x \in R^n} \Phi_{\mu}(x, s) &:= f(x) - \mu \sum_{i \in \mathcal{I}} \log s_i, \\ c_i(x) &= 0 \quad i \in \mathcal{E}, \\ c_i(x) - s_i &= 0 \quad i \in \mathcal{I}, \end{aligned} \quad (5)$$

where $\mu > 0$ is the barrier parameter. The Lagrangian function associated with Equation (5) is

$$\mathcal{L}(x, s, \lambda, \mu) = \Phi_{\mu}(x, s) + \lambda_{\mathcal{E}}^T c_{\mathcal{E}}(x) - \lambda_{\mathcal{I}}^T (c_{\mathcal{I}}(x) - s). \quad (6)$$

For convenience, let $A_{\mathcal{E}}$ and $A_{\mathcal{I}}$ denote the Jacobian matrices of the mappings $c_{\mathcal{E}}(x)$ and $c_{\mathcal{I}}(x)$, respectively. Then, we can write the first-order optimality conditions for Equation (5) as follows:

$$\begin{aligned} \nabla f(x) + A_{\mathcal{E}}^T \lambda_{\mathcal{E}} - A_{\mathcal{I}}^T \lambda_{\mathcal{I}} &= 0, \\ S \Lambda_{\mathcal{I}} e - \mu e &= 0, s \geq 0, \lambda_{\mathcal{I}} \geq 0 \quad (7) \\ c_i(x) &= 0 \quad i \in \mathcal{E}, \\ c_i(x) - s_i &= 0 \quad i \in \mathcal{I}. \end{aligned}$$

At each iteration, a primal-dual IPM obtains a search direction by computing the

linearized Newton direction for the nonlinear system of Equation (7) as follows [25–27]:

$$\begin{pmatrix} W(z, \lambda, \mu) & A(x)^T \\ A(x) & 0 \end{pmatrix} \begin{pmatrix} \Delta z \\ \Delta \lambda \end{pmatrix} = - \begin{pmatrix} \nabla_z \mathcal{L}(z, \lambda, \mu) \\ c(z) \end{pmatrix}, \quad (8)$$

where

$$\begin{aligned} z &= \begin{pmatrix} x \\ s \end{pmatrix}, \Delta z = \begin{pmatrix} \Delta x \\ \Delta s \end{pmatrix}, \\ \Delta \lambda &= \begin{pmatrix} \Delta \lambda_{\mathcal{E}} \\ \Delta \lambda_{\mathcal{I}} \end{pmatrix}, c(z) = \begin{pmatrix} c_{\mathcal{E}}(x) \\ c_{\mathcal{I}}(x) - s \end{pmatrix}. \end{aligned} \quad (9)$$

and

$$\begin{aligned} A(x) &= \begin{pmatrix} A_{\mathcal{E}} & 0 \\ A_{\mathcal{I}} & -I \end{pmatrix}, \\ W(z, \lambda, \mu) &= \begin{pmatrix} \nabla_{xx}^2 \mathcal{L}(z, \lambda, \mu) & 0 \\ 0 & -S^{-1} \Lambda_{\mathcal{I}} \end{pmatrix}. \end{aligned} \quad (10)$$

After solving Equation (8), we update the new iterate by

$$z^+ = z + \alpha_z \Delta z, \quad \lambda^+ = \lambda + \alpha_{\lambda} \Delta \lambda, \quad (11)$$

where $\alpha_z, \alpha_{\lambda}$ are step lengths that are chosen to keep s and $\lambda_{\mathcal{I}}$ strictly positive. Then a backtracking line search is used to compute the final step length, which provides sufficient decrease of a merit function or ensures acceptability by a filter. This simple approach is the basis for line search IPMs; however, it should be modified for the nonconvex problem to prevent convergence to nonstationary point. The optimality test is based on a merit function that measures the violation of the optimality conditions

$$m(x, s, \lambda) = \max \left\{ \|\nabla f(x) + A_{\mathcal{E}}^T \lambda_{\mathcal{E}} - A_{\mathcal{I}}^T \lambda_{\mathcal{I}}\|, \|S \Lambda_{\mathcal{I}} e\|, \|c_{\mathcal{E}}(x)\|, \|c_{\mathcal{I}}(x) - s\| \right\}$$

A generic framework for primal-dual IPMs is summarized as follows:

Primal-Dual interior point algorithm.

1. Choose (x_0, s_0, λ_0) such that $s_0 > 0, \lambda_{\mathcal{I}}^0 > 0$ and select an initial barrier parameter $\mu_0 > 0$.

2. For $k = 0, 1, \dots$, do the following:

- If $m(x, s, \lambda) \leq \text{tol}$, then stop (The optimality test).
- Compute the search direction $d = (\Delta z; \Delta \lambda)$ by solving Equation (8);
- Compute the step length $\hat{\alpha}_s$ and $\hat{\alpha}_{\lambda_{\mathcal{I}}}$ by

$$\hat{\alpha}_s = \frac{-1}{\min(S_k^{-1} \Delta s_k, -1)},$$

$$\hat{\alpha}_{\lambda_{\mathcal{I}}} = \frac{-1}{\min(\Lambda_k^{-1} \Delta \lambda_{\lambda_{\mathcal{I}}}, -1)}.$$

- Find $\tau_k \in (0, 1]$ and $\alpha \in (0, 1]$ such that

$$m(x + \alpha \Delta x, s + \alpha_s \Delta s, \lambda_{\mathcal{E}} + \alpha \Delta \lambda_{\mathcal{E}}, \lambda_{\mathcal{I}} + \alpha_{\lambda_{\mathcal{I}}} \Delta \lambda_{\mathcal{I}}) \leq m(x, s, \lambda) + \beta \alpha \nabla m(x, s, \lambda)^T d$$

for some $\beta \in (0, 1)$ where $\alpha_s = \min(1, \tau_k \hat{\alpha}_s)$, $\alpha_{\lambda_{\mathcal{I}}} = \min(1, \tau_k \hat{\alpha}_{\lambda_{\mathcal{I}}})$.

- Update the iterate by

$$x_{k+1} = x_k + \alpha \Delta x_k, \quad s_{k+1} = s_k + \alpha_s \Delta s_k,$$

$$(\lambda_{\mathcal{E}})_{k+1} = (\lambda_{\mathcal{E}})_k + \alpha (\Delta \lambda_{\mathcal{E}})_k,$$

$$(\lambda_{\mathcal{I}})_{k+1} = (\lambda_{\mathcal{I}})_k + \alpha_{\lambda_{\mathcal{I}}} (\Delta \lambda_{\mathcal{I}})_k.$$

Update the barrier parameter μ_{k+1} ¹.

GLOBAL AND LOCAL CONVERGENCE OF THE ALGORITHM

As it is known, one of the main features of IPMs that distinguishes them from many other optimization methods is their polynomial iteration complexity. This feature holds for some NLPs as well. (see Monteiro and Adler, Wright, and Ye [17,18,28] and reference therein). Nesterov and Nemirovski [13], showed that IPMs enjoy polynomial

complexity for linear programming problems over the intersection of an affine set and the so-called self-dual cone, which includes the second-order cone and the cone of semidefinite matrices. These classes of problems allow us to find a global optimal solution of some nonconvex quadratically constrained quadratic and fractional quadratic problems [29,30].

For generic convex and nonconvex programming problems, however, the theoretical results on IPMs are weaker. In both the theoretical analysis and practical implementation of primal–dual IPMs for nonconvex NLPs, a key is how to ensure convergence from a general starting point. One of the most popular choices is to require a sufficient decrease in a merit function that encourages the early iterates to move toward the trajectory. However, it should be noted that the choice of an appropriate merit function for nonconvex problems is nontrivial. For example, $\|F_{\mu}(v)\|$ is the one that has been used within many algorithms, where $F_{\mu}(v)$ is the function on the left-hand side of Equation (7). But it only ensures convergence to points satisfying the first-order conditions. However, since many primal–dual algorithms try to find points satisfying second-order necessary conditions, this merit function is not appropriate for such a purpose. For example, in Conn *et al.* [31] the authors have used the barrier function as the merit function.

For illustration, in the sequel we present a specific variant of primal–dual IPMs that is globally convergent under certain conditions [19]. Let us denote the function on the left-hand side of Equation (4) by

$$F(x, s, \lambda) = \begin{bmatrix} G(x, s, \lambda) \\ S \Lambda_{\mathcal{I}} e \end{bmatrix},$$

and

$$G(x, s, \lambda) = \begin{bmatrix} \nabla_x L(x, s, \lambda) \\ c_{\mathcal{I}} \\ c_{\mathcal{E}} - s \end{bmatrix}.$$

Further, for simplicity, let $v = (x, s, \lambda)$ and $v(\alpha) = v + \alpha \Delta v$, where

$$F'(v) \Delta v = -F(v) + \mu \hat{e}, \quad (12)$$

$\hat{e} = (0, \dots, 0, 1, \dots, 1)$ with p ones and $p = |\mathcal{E}|$. For a given starting point v_0 with $(s_0, \lambda_{\mathcal{I}}^0) > 0$,

¹See the section titled “Implementation Strategies and Software Development” for more details on the barrier parameter updating strategy.

let

$$\tau_1 = \frac{\min(S_0 \Lambda_{\mathcal{I}}^0 e)}{[s_0^T \lambda_{\mathcal{I}}^0 / p]}, \quad \tau_2 = \frac{s_0^T \lambda_{\mathcal{I}}^0}{\|G(v_0)\|}.$$

Define

$$f^I(\alpha) = \min(S(\alpha) \Lambda_{\mathcal{I}}(\alpha)) - \gamma \tau_1 \frac{s(\alpha)^T \lambda_{\mathcal{I}}(\alpha)}{p},$$

$$f^{II}(\alpha) = s(\alpha)^T \lambda_{\mathcal{I}}(\alpha) - \gamma \tau_2 \|G(v(\alpha))\|,$$

where $\gamma \in (0, 1)$ is a constant. It can be easily shown that if α_k are chosen such that $f^I(\alpha) \geq 0$, for all $\alpha \in [0, \alpha_k]$, then at every iteration we have $(s_k, \lambda_{\mathcal{I}}^k) > 0$ and

$$\frac{\min(S_k \Lambda_{\mathcal{I}}^k e)}{[(s_k)^T \lambda_{\mathcal{I}}^k / p]} \geq \gamma_k \tau_1, \quad \gamma_k \in (0, 1).$$

On the basis of the above observation, to choose a suitable size α_k , we require α_k to satisfy the following relations:

$$f^i(\alpha_k) \geq 0, i = I, II, \quad f^I(\alpha_k) \geq 0, \forall \alpha \in [0, \alpha_k].$$

For $i = I, II$, let

$$\alpha_i = \max_{\alpha \in [0, 1]} \{\alpha : f^i(\alpha') \geq 0, \forall \alpha' \leq \alpha\}. \quad (13)$$

In other words, α' is either one or the smallest positive root for the functions $f^i(\alpha)$ in $(0, 1]$. One can show that $\alpha^i > 0$. Since $f^I(a)$ is piecewise quadratic, α^I can be found easily.

The globalized algorithm is a perturbed and damped Newton method combined with a backtracking line search. The merit function used for the line search is the squared l_2 -norm of the residual, that is,

$$\phi(v) = \|F(v)\|^2.$$

Let ϕ_k denote the value of the function $\phi(v_k)$ and $\phi_k(\alpha)$ denote $\phi(v_k + \alpha \Delta v_k)$. Under mild conditions, one can show that the perturbed Newton step,

$$\Delta v_k = -F'_{\mu_k}(v_k)^{-1} F_{\mu}(v_k)$$

is a descent direction for the merit function $\phi(v)$.

The globalized algorithm in *El-Bakry et al.* [19] is described as follows.

A globalized algorithm.

Step 0. Choose $v_0 = (x_0, s_0, \lambda^0)$ such that $(s_0, \lambda_{\mathcal{I}}^0) > 0$, $\rho \in (0, 1)$, and $\beta \in (0, \frac{1}{2}]$. Set $k = 0$, $\gamma_{k-1} = 1$, and compute $\phi_0 = \phi(v_0)$. For $k = 0, 1, \dots$, do the following steps.

Step 1. If $\phi_k \leq \epsilon_{\text{exit}}$, stop.

Step 2. Choose $\sigma_k \in (0, 1)$; for $v = v_k$, compute the perturbed Newton direction Δv_k from Equation (12) with $\mu_k = \sigma_k \frac{s_k^T \lambda_{\mathcal{I}}^k}{p}$.

Step 3. Step length selection:

- Choose $\frac{1}{2} \leq \gamma_k \leq \gamma_{k-1}$: compute $\alpha^i, i = I, II$, from (13) and let

$$\bar{\alpha}_k = \min(\alpha^I, \alpha^{II}).$$

- Let $\alpha_k = \rho^t \bar{\alpha}_k$, where t is the smallest nonnegative integer satisfying

$$\phi_k(\alpha_k) \leq \phi_k(0) + \alpha_k \beta \phi'_k(0).$$

Step 4. Let $v_{k+1} = v_k + \alpha_k \Delta v_k$ and $k = k + 1$ and go to Step 1.

For a given $\epsilon \geq 0$, let us define

$$\Omega(\epsilon) = \left\{ v : \epsilon \leq \phi(v) \leq \phi_0, \min(S \Lambda_{\mathcal{I}} e) / (s^T \lambda_{\mathcal{I}} / p) \geq \frac{\tau_1}{2}, s^T \lambda_{\mathcal{I}} / \|G(v)\| \geq \frac{\tau_2}{2} \right\}.$$

We now state some assumptions that are needed to prove the global convergence of the algorithm.

(C1) In the set $\Omega(0)$, the functions $f(x), c_{\mathcal{I}}(x), c_{\mathcal{E}}(x)$ are twice-continuously differentiable and the derivative of $G(v)$, is Lipschitz continuous with constant L . Moreover, the columns of $\nabla c_{\mathcal{I}}(x)$ are linearly independent.

(C2) The iteration sequence $\{x_k\}$ is bounded.²

²This can be ensured by imposing box constraints $-M \leq x \leq M$ for sufficiently large $M > 0$.

- (C3) The matrix $\nabla^2(x, s, \lambda) + \nabla c_{\mathcal{E}}(x)S^{-1}\Lambda_T\nabla c_{\mathcal{E}}^T(x)$ is invertible for v in any compact subset of $\Omega(0)$, where s is bounded away from zero.
- (C4) Let I_s^0 be the index set $\{i : 1 \leq i \leq p = |\mathcal{E}|, \liminf [s_k]_i = 0\}$. Then, the set of gradients $\{\nabla c_1(x_k), \dots, \nabla c_{|\mathcal{I}|}(x_k), \nabla c_i(x_k), i \in I_s^0\}$ is linearly independent for sufficiently large k .

The following theorem is from El-Bakry *et al.* [19].

Theorem 1. *Let $\{v_k\}$ be generated by the globalized algorithm, with $\epsilon_{\text{exit}} = 0$ and $\{\sigma_k\} \subset (0, 1)$ bounded away from zero and one. Under assumptions (C1)–(C4), $\{F(v_k)\}$ converges to zero and, for any limit point $v^* = (x^*, s^*, \lambda^*)$ of $\{v_k\}$, x^* is a KKT point of problem (1).*

We mention that if (C1)–(C4) are violated, then this particular algorithm may not converge. For example in Wachter and Biegler [32], a class of one-dimensional examples are identified for which certain line-search barrier-SQP methods fail to find a feasible point and do not converge to a meaningful point. This is caused by the failure of regularity condition (C4). There are many variants of IPMs that use regularization and relatively weaker assumptions other than (C1)–(C4) to ensure global convergence. For more details, we refer to the articles by Ulbrich *et al.* [20], and Yamashita [21], Akrotirianakis and Rustem [33], Griva *et al.* [34] and the references therein.

Local convergence results for primal–dual IPMs have been given by Wright [35], Conn *et al.* [31], El-Bakry *et al.* [19], Yamashita *et al.* [21,36], and Benson *et al.* [25]. The local convergence results of these methods are inherited from the use of Newton’s method to generate search directions. As with SQP methods, the drawbacks of Newton’s method are also inherited. Global convergence results have been discussed by El-Bakry *et al.* [19], Yamashita [21], and Akrotirianakis and Rustem [33]. Here, we present only the local convergence of the

algorithm from El-Bakry *et al.* [19]. Let $\mathcal{A}(x^*)$ be the set of active constraints. The following assumptions are crucial:

1. There is a solution (x^*, s^*, λ^*) satisfying the KKT conditions for Equation (1).
2. The Hessian matrices $\nabla^2 f(x), \nabla^2 c_{\mathcal{E}}(x), \nabla^2 c_{\mathcal{I}}(x)$ exist and are locally Lipschitz continuous at x^* .
3. The set $\{\nabla c_1(x^*), \dots, \nabla c_{|\mathcal{E}|}(x^*)\} \cup \{\nabla c_i(x^*), i \in \mathcal{A}(x^*)\}$ is linearly independent.
4. For all $\eta \neq 0$, $\nabla c_i(x^*)^T \eta = 0$, $i \in \mathcal{E} \cup \mathcal{A}(x^*)$ we have $\eta^T \nabla_{xx}^2 \mathcal{L}(x^*) \eta > 0$.
5. For all $i \in \mathcal{I}$, $s_i + \lambda_i > 0$.

Theorem 2. [19] *Suppose for Equation (1) at $v^* = (z^*, \lambda^*, \mu^*)$ assumptions 1 to 5 hold. Given $\hat{\tau} \in (0, 1)$, there exists a neighborhood D of v^* and a constant $\hat{\sigma}$ such that for any v^0 in D and $\tau_k \in [\hat{\tau}, 1)$ and $\sigma_k \in (0, \hat{\sigma})$, primal–dual interior point algorithm is well defined and iteration sequence generated by it converges Q -linearly to v^* .*

More results on local convergence analysis can be found in the articles by Akrotirianakis and Rustem [33] Griva *et al.* [34] Ulbrich *et al.* [20].

IMPLEMENTATION STRATEGIES AND SOFTWARE DEVELOPMENT

As shown in the previous section, we need to update the iterate carefully to ensure the convergence of the algorithm for NLPs. In this section, we review some other updating strategies that are crucial for the success of primal–dual IPMs in both theory and practice.

We start with the procedure for updating the barrier parameter μ . Two types of update strategies have been considered in the literature: adaptive and monotone. Adaptive strategies [19,20,37] allow changes in the barrier parameter at every iteration, and are often efficient in practice, but they generally do not guarantee the global convergence of the algorithm. For example, the algorithms in El-Bakry *et al.* [19] and Ulbrich *et al.*

[20] only converge to stationary points. This is because these algorithms enforce only reduction of a measure of stationarity but do not necessarily reduce the objective function value. The most important monotone strategy is the so-called Fiacco–McCormick approach that fixes the barrier parameter until an approximate solution of the barrier problem is found. It has been employed in various nonlinear interior algorithms [21,24,38] and has been implemented, for example, in the IPOPT and KNITRO software packages. The Fiacco–McCormick strategy provides a framework for establishing global convergence [39,40], but sometimes suffers from several limitations. For example, it could be very sensitive to the choice of the initial point, the initial value of the barrier parameter, and the scaling of the problem, and it is often unable to recover quickly when the iterates approach the boundary of the feasible region prematurely. The numerical experiments of Nocedal *et al.* [41] with IPOPT and KNITRO suggests that more dynamic update strategies are needed to improve the efficiency of nonlinear IPMs. The two widely used adaptive approaches are Mehrotra’s technique and the one used in LOQO [23,24]. Computational experiments show that the adaptive strategies outperform the monotone approach but they are not very robust. To resolve this problem, Nocedal *et al.*, [41] introduced an efficient adaptive strategy using a linear quality function within Mehrotra’s predictor corrector algorithm with a globalization framework. The role of the quality function is to determine the best value of σ in $\mu = \sigma \frac{s^T w}{n}$ by penalizing large errors in the KKT conditions.

Another key step in primal–dual IPMs is that of solving the Newton system for a search direction. An effective implementation must exploit the sparsity or other structures in the matrix. The Newton system in primal–dual IPMs is well defined when the matrix $W(z, \lambda, \mu)$ is nonsingular. Several conditions such as the second-order optimality, strict complementarity, and regularity conditions can guarantee the nonsingularity of $W(z, \lambda, \mu)$ in a small neighborhood of the optimal solution. When the iterate is far from the solution, we may regularize the Hessian

$\nabla_{xx}^2 \mathcal{L}(z, \lambda, \mu)$, if necessary, to get a nonsingular $W(z, \lambda, \mu)$ [42,43]. An alternative approach is to use a safe-guarded trust region step to stabilize the iteration, which can be found in Waltz *et al* [44].

As it is known, merit functions are usually used to measure the progress of the algorithm. Another approach to ensure the convergence of primal–dual IPMs for NLPs is the so-called filter method. Differing from the methods using merit functions, the filter methods separately deal with the two primary goals: reduce the objective function value and the infeasibility. Such a strategy makes the filter methods insensitive to the choice of merit functions and allows more freedom in selecting the next trial point. More details on filter methods and their numerical performance can be found in Vanderbei [23], Wachter and Biegler [24], Benson *et al.* [45], Fletcher *et al.* [46].

The above discussed strategies have been implemented in several software packages and successfully applied to solve large-scale nonlinear and nonconvex programming problems. These include IPOPT [24], KNITRO [22], and LOQO [23]. One may find information regarding these packages on NEOS server (<http://www-neos.mcs.anl.gov/neos/>), which provides online solution for optimization problems.

CONCLUSIONS

The research on IPMs has reshaped many areas in mathematical programming and still continues to improve the optimization theory and methods. In this article we have given a brief overview of primal–dual IPMs for NLPs. We have presented some global and local convergence results. Key implementation strategies have been discussed. More details on the theory, algorithms, convergence results, practical performance of algorithms can be found in the list of references and related papers.

INTERIOR-POINT LINEAR PROGRAMMING SOLVERS

HANDE Y. BENSON
Drexel University,
Philadelphia,
Pennsylvania

We present an overview of available software for solving linear programming (LP) problems using interior-point methods. We consider both open-source and proprietary commercial codes, including BPMPD [1,2], COIN Linear Program code (CLP) [3], FortMP [4], GIPALS32 [5], GNU Linear Programming Kit (GLPK) [6], HOPDM [7,8], IBM ILOG CPLEX [9], LINDO [10], LIPSOL [11], LOQO [12], Microsoft Solver Foundation [13], MOSEK [14], PCx [15], SAS/OR [16], and Xpress Optimizer [17].

Some of the codes discussed include primal and dual simplex solvers as well, but we focus the discussion on the implementation of the interior-point solver. For each solver, we present types of problems solved, available distribution modes, input formats and modeling languages, as well as algorithmic details, including problem formulation, use of higher corrections, presolve techniques, ordering heuristics for symbolic Cholesky factorization, and the specifics of numerical factorization. Many of the solvers allow user-control over some algorithmic details such as the type of presolve techniques applied to the problem and the choice of ordering heuristic. As the following discussion will show, the solvers tend to all have similar characteristics, and performance differences are generally due to subtle changes in the presolve phase, the implementation of the linear algebra routines, and other special considerations, such as scaling, to promote numerical stability.

We start with a short discussion of input formats and modeling languages available for LPs. Then, we will present details of a wide-range of interior-point codes.

INPUT FORMATS AND MODELING LANGUAGES FOR LINEAR PROGRAMMING

For a standard LP of the form

$$\begin{array}{ll} \text{maximize} & c^T x \\ \text{subject to} & Ax = b \\ & x \geq 0, \end{array} \quad (1)$$

it suffices to pass the matrix A and the vectors b and c to the solver for a full-description of the problem. Of course, the general form of an LP can incorporate inequality constraints as well as bounds on variables, but such deviations from Equation (1) require either the user to include slack variables to convert the problem to Equation (1) or the modeling mechanism to accommodate the specification of additional data vectors, such as upper and lower bounds on the variables and indicator arrays for constraint types.

We will discuss two types of modeling mechanisms here: input formats, which allow for a specifically formatted means to enter problem data which can then be interpreted by the solver, and modeling languages, which allow for a flexible algebraic expression of the model as well as the data and are accompanied by full-fledged modeling systems. Many of the solvers we will discuss can also be used as callable libraries, so the model can be expressed in a variety of programming languages, such as C, Fortran, and Java, and various routines implemented in the solver library can be called to load and solve the LP.

MPS Format

Mathematical Programming System (MPS), is the oldest input format for LPs and is the most widely accepted input format among both academic and commercial solvers. We refer the reader to Ref. 18 for a detailed description and provide a brief overview here. MPS uses ASCII text files to store the problem and is modeled after punch cards. Header cards specify which component of Equation (1) is to be introduced next. The ROWS card

specifies the names and types of objective functions and constraints, the COLUMNS card specifies variable names and the entries of c and A , the RHS card specifies the elements of the right-hand side vector b , and the BOUNDS card specifies any upper and lower bounds on x . The format is column-oriented: for example, rather than using the ROWS card to enter each of the variable coefficients appearing in a constraint, the coefficients of a single variable as it appears in the objective function and any constraints are listed together in the COLUMNS card. All model components are assigned names of eight characters or less, and the information is presented in fields that begin in columns 2, 5, 15, 25, 40, and 50. Each data element has to be individually listed in the file, and at most two elements can be specified per line.

Because of its punch card format, MPS files may be hard for a user to read, but it is very easy for a solver or a modeling environment to read and write in this format. With additional card types, the format has been extended to quadratic problems (QPs) and mixed-integer programming (MIPs), and free format variations exist, as well.

LP Format

The LP input format is an alternative to the MPS format that allows for entering algebraic expressions to describe the problem. While it may be more natural to read a model in LP format, it is nonetheless not a standardized format and different solvers/parsers may interpret the problem components differently. Two common variants are CPLEX LP format and Xpress LP format.

As in the MPS format, the model is expressed in an ASCII text file, and there are specified sections to express each type of model component. Each section starts with a header, and there are Objectives, Constraints, Bounds, and Variable Type sections available for LPs. Within the Constraints section, for example, each constraint is given a name, followed by a colon, and then the constraint expression, and each constraint is written on a separate line. Unlike the MPS format, there are no fixed field widths for separating problem components. For further

details of the LP format, we refer the reader to Ref. 19.

AMPL

AMPL [20] is a modeling language for algebraically expressing a wide-range of optimization problems. Originally developed at Bell Laboratories, it has become the standard for formulating highly complex problems. AMPL is more than just a compiler for the optimization model, as it also includes pre and postprocessing routines, as well as first- and second-order differentiation capabilities for nonlinear programming NLPs. The indexing and looping constructs in AMPL allow for a concise expression of large-scale LPs, and the processor allows for the separation of the model and data into multiple files. Many LP solvers have AMPL interfaces, and a tool for converting MPS format to AMPL, *m2a*, is also available.

GAMS

GAMS [21], or the General Algebraic Modeling System, is another widely used modeling system for optimization. Originally funded by The World Bank, it is the oldest modeling language for mathematical programming, and it is currently developed and distributed by the GAMS Development Corporation. It is similar to AMPL in terms of capabilities, and the GAMS-AMPL service available through the NEOS Server [22] allows for the solution of models formulated in GAMS by AMPL solvers.

Other Input Formats and Modeling Languages

Almost every LP solver to be discussed accepts models expressed in one or more of the four input formats and modeling languages mentioned above. There are several other means of communicating LPs to the solvers and we will briefly mention them here:

- LP-Plain (LPP), is a variant of the LP input format;
- Optimization Problem Format (OPF), is a variant of the CPLEX LP input format;

- Mathematical Programming Language (MPL), is an algebraic language and modeling system;
- Optimization Modeling Language (OML), is the input format used by Microsoft Solver Foundation.

INTERIOR-POINT LP SOLVERS

In this section, we will provide an overview of some of the most widely used LP solvers. The solvers are presented in alphabetical order.

BPMPD

BPMPD [1,2] is a solver developed by Cs. Mészáros for solving LPs and convex QPs. It is written in C and is available both as an executable and as a callable library. It accepts input in LP and MPS formats for LP and in QPs format for convex QP. The solver can also be called from AMPL and is available for use on the NEOS Server [22]. There is a MEX interface [23] to use the callable library from within Matlab.

BPMPD implements an infeasible interior-point method as described in Refs 24 and 25, and uses Mehrotra's [26] predictor-corrector framework and barrier parameter updates, along with higher order corrections [27]. The strength of the solver is in the extensive linear algebra routines, particularly for presolve and Cholesky factorization. During presolve, BPMPD removes empty rows and columns, singleton rows, and redundant variable bounds and constraints, eliminates free or implied free variables, substitutes duplicated variables, and sparsifies the constraint matrix. A heuristic is used to decide between the normal equation and augmented system approaches for solving for the step directions, and minimum degree and minimum local-fill options are available for symbolic ordering. For the numerical factorization, a left-looking supernodal factorization algorithm is implemented, and a supernodal backsolve is used. During both factorization and backsolve, loop unrolling is used.

CLP

CLP [3] is an open-source solver distributed by the COIN-OR project [28]. It is implemented in C++ and is available as an executable and a callable library. It can also be used over the NEOS server [22] to solve LPs written in MPS format. While mainly a simplex solver, CLP also implements a barrier method for handling LPs and convex QPs. We focus here on the barrier code.

CLP implements Mehrotra's [26] predictor-corrector algorithm and uses higher order corrections [27]. The distribution contains native code for sparse Cholesky factorization, but it is recommended that a third party factorization code be used. There are interfaces for WSSMP [29], which provide parallel enabled ordering and factorization, TAUCS [30], which uses third party ordering and implements parallel enabled factorization, and AMD [31], which provides an approximate minimum degree ordering and can be used with CLP's native code for factorization.

FortMP

FortMP [4] is a commercial solver distributed by Optirisk systems. It can handle LPs and convex QPs, as well as mixed-integer linear and QPs. The code is written in Fortran 77 and accepts models written in AMPL as well as input in MPS format. It is available for use on the NEOS Server [22]. FortMP is primarily a simplex solver and an interior-point method implementation, referred to as *FortMP IPM*, is included for large-scale LPs and convex QPs.

FortMP IPM is an infeasible primal-dual interior-point method. There are three alternatives implemented for step direction calculations: an affine scaling algorithm, a barrier algorithm, and a predictor-corrector algorithm. According to the documentation, the latter is recommended for most LPs, whereas the affine scaling algorithm is to be preferred for extremely sparse problems, and the barrier algorithm is backup in case of failure. For barrier parameter updates, the user can choose between a multiple of the current duality gap and the updating scheme of [26]. The code includes native routines for

Cholesky factorization and allows for the use of supernodes.

GIPALS32

GIPALS32 [5] is a commercial solver distributed by Optimalon software. It is a Windows-based callable library and includes an application programming interface (API). GIPALS32 is the solver library for the LP environment GIPALS, which uses a graphical user interface that includes tables and forms for easily entering problem data and can read and write MPS files.

GIPALS32 implements Mehrotra's [26] predictor-corrector algorithm and uses higher order corrections [27].

GLPK

GLPK [6] is a toolkit for LP and MIP, distributed by the Free Software Foundation, Inc. as part of the GNU Project under the GNU General Public License. It is written in ANSI C and is available as a callable library. The solver routine within the toolkit is *glpsol*. GLPK includes both simplex and interior-point codes, and accepts input in the GNU MathProg modeling language, a subset of the AMPL language, and in GAMS as CoinGLPK. It is available for use on the NEOS Server [22].

GIPALS32 implements an infeasible primal-dual interior-point method with Mehrotra's [26] predictor-corrector algorithm. For symbolic Cholesky factorization, it has multiple ordering options, including quotient minimum degree and approximate minimum degree, and includes interfaces for third party ordering codes AMD [31] and COLAMD [32]. One should note, however, that the simplex methods implemented within GLPK are more mature than the interior-point method, which does not include some important features such as dense column processing and scaling to provide numerical stability.

HOPDM

HOPDM [7,8] is a package for solving large-scale linear, convex quadratic, and convex non-LP problems, written by Gondzio and

distributed by the University of Edinburgh. It is written in C and is available as an executable and a callable library. It accepts models written in MPS format and can be called from AMPL.

HOPDM implements an infeasible primal-dual interior-point method. It uses multiple centrality correctors [27], and the number of correctors is chosen automatically to reduce the overall solution time. HOPDM includes an extensive presolve routine [33,34], and chooses between the normal equations and the augmented system approach in order to improve the efficiency of the factorization method [35]. Symbolic Cholesky factorization approaches include multiple minimum degree ordering [36] and the quotient tree minimum degree ordering [37]. New versions also include iterative solvers for the Newton system. The algorithm is also capable of warm-starting [38] after a data perturbation in the objective, right-hand side, or the constraint matrix.

IBM ILOG CPLEX

CPLEX [9] is a package for solving LPs, convex QPs, problems with convex quadratic constraints, integer, and MIPs. It is currently distributed as an executable and a callable library by ILOG, an IBM company. It accepts models written in MPS and CPLEX LP input formats and can be called from ILOG OPL Development Studio, AMPL, GAMS, MPL, Matlab, Microsoft Excel, and Python. A parallel implementation is also available.

CPLEX implements three algorithms: a primal simplex method, a dual simplex method, and a primal-dual logarithmic barrier method. We will focus on the barrier method here, which is a primal-dual interior-point method using the predictor-corrector framework [26]. It uses multiple centrality correctors [27], and the maximum number of correctors can be chosen by the user or automatically determined by the algorithm. For symbolic Cholesky factorization, there are three options: approximate minimum degree, approximate minimum local fill, and nested dissection. CPLEX can automatically choose the best ordering heuristic to use, or this can be user-specified. The numerical factorization can be performed out-of-core

to improve memory usage and efficiency, and special handling of dense columns is available.

LINDO Systems

LINDO Systems, Inc. distributes three software packages [10] for mathematical programming: LINDO API, the callable library of solvers; LINGO, the modeling system for building and solving problems; and What's Best, the Microsoft Excel add-in. These packages can model and solve a variety of different types of optimization problems, including LPs, QPs, and NLPs. For LPs, the LINDO API can handle problems written in the MPS input format and in LINDO, and What's Best accepts spreadsheet models developed using Microsoft Excel. Besides the interior-point method, the packages also contain implementations of the primal and dual simplex methods. A parallel implementation is available.

LIPSOL

LIPSOL [11], or LP Interior-Point SOLvers, is a Matlab-based package for solving LPs, written and distributed by Zhang. It takes advantage of the sparse matrix operations available in Matlab and also uses Fortran and C routines linked via MEX. Besides problem data stored in a MAT file, LIPSOL can also accept LPs written in MPS and LPP input formats.

LIPSOL implements a primal-dual infeasible interior-point method and uses Mehrotra's predictor–corrector framework [26]. The barrier parameter updates are a modified version of that in Ref. 26. Instead of using Matlab's built-in sparse Cholesky factorization code, which would need to be modified for numerical stability, LIPSOL uses two Fortran codes: the multiple minimum degree ordering package [39] and the sparse Cholesky factorization package [40]. For efficiency, dense columns are split, so a preconditioned conjugate gradient approach is used to ensure numerical stability.

LOQO

LOQO [12] is a solver for LPs, QPs, and NLPs, written by Vanderbei and distributed

by Princeton University. It is written in C and is available as an executable or a callable library. It accepts LPs written in the MPS input format and can be called from AMPL and Matlab, via a MEX interface. It is available for use over the NEOS Server [22].

Despite its current focus as an NLP code, LOQO was originally developed as an infeasible interior-point method for LPs and convex QPs. It implements an infeasible interior-point method and uses Mehrotra's predictor–corrector framework [26]. Free variables and equality constraints are split and allow for the use of primal or dual orderings in the symbolic Cholesky factorization. Furthermore, priorities, or tiers, are assigned to the columns of the matrix [41] by constraint and variable types, and within each tier, minimum local fill and multiple minimum degree orderings [42] are available. For the numerical factorization, supernodes are used with loop unrolling to improve efficiency.

Microsoft Solver Foundation

Microsoft Solver Foundation [13] is an integrated modeling and solver environment for LPs, convex QPs, second-order cone programming problems, and integer and MIPs, as well as constraint programming and unconstrained non-LP problems. The models can be expressed in OML format. For LP, the environment contains both a simplex and an interior-point solver, and we focus here on the latter.

Microsoft Solver Foundation implements a primal-dual interior-point method that solves a homogeneous self-dual model. Each equality constraint is split into a range constraint with equal bounds, and free variables are handled as inequality constraints, that is, a free variable x_j is replaced by the requirement that $x_j + s_j \geq 0$ with $s_j \geq 0$. Any numerical issues arising from such a treatment of equality constraints and free variables are further alleviated by the regularization scheme of [43]. The normal equations approach is used when solving the Newton system. The default ordering method for Cholesky factorization is the approximate minimum degree ordering, but an option to switch to the approximate minimum fill is

also available. For the numerical factorization, a left-looking supernodal factorization algorithm is implemented, and it is multi-core-enabled.

MOSEK

MOSEK [14] is a package for solving LPs, conic QPs, general convex NLPs, and mixed-integer problems, distributed by MOSEK ApS. It accepts LPs written in the MPS, LP, and OPF input formats and can be called from AMPL and Matlab. APIs for use with programs written in C/C++, C#, .NET, Java, Delphi, and Python are provided. It is also available for use over the NEOS Server [22]. Additionally, there is a parallel implementation of MOSEK [44].

MOSEK implements the homogeneous self-dual algorithm described in Ref. 45. Prior to solving the LP, a presolve phase is used to check for and remove redundancies and linear dependence, eliminate fixed variables, substitute out free variables, and reduce problem size. A dualizer routine decides whether to solve the primal or the dual LP using heuristics. Scaling is performed by multiplying the necessary constraints and variables by constants to improve numerical stability. For the step direction calculations, Mehrotra's predictor-corrector framework [26] is used along with higher-order corrections [27]. The solution of the Newton system is done via the normal equations approach. The default ordering method for Cholesky factorization is the approximate minimum degree heuristic [31], but implementations of multiple minimum degree and minimum local-fill are also provided. For the numerical factorization, supernodes are split into blocks to improve cache usage, and up to 16-way loop unrolling is available to further increase efficiency. A push Cholesky framework, where an iteration consists of a particular column performing all its updates on all other remaining columns to the right, is used.

PCx

PCx [15] is an LP solver distributed by the Optimization Technology Center at Argonne

National Laboratory and Northwestern University. The code is written in C and incorporates a modified version of Ng and Peyton's sparse Cholesky factorization package, written in Fortran 77. It accepts LPs written in the MPS input format and can be called from AMPL and Matlab. Additionally, a graphical user interface (PCxGUI) written in Java is available. PCx is available for use over the NEOS Server [22]. A parallel implementation, pPCx, [46] also exists.

PCx implements Mehrotra's predictor-corrector algorithm [26] and also uses higher-order corrections [27]. The scaling technique of Curtis and Reid [47], which minimizes the deviations of the nonzero elements of the coefficient matrix A from 1.0, is applied prior to the solution to improve the numerical stability of the code. A presolver removes redundancies, empty rows and columns, singleton rows, and fixed variables, eliminates singleton columns, and substitutes duplicated variables. For solving the Newton system, PCx defaults to the normal equations approach, and uses Ng and Peyton's sparse Cholesky factorization package [40], modified to handle small pivot elements. The ordering scheme is multiple minimum degree as described in Refs 36 and 48. For the numerical factorization, supernodes are split into blocks to make better use of hierarchical memory, and loop unrolling further increases efficiency.

SAS/OR

SAS/OR software [16] is a commercial package which includes codes for mathematical programming, project and resource scheduling, and discrete event simulation. It is distributed by SAS Institute, Inc. Models are expressed in the OptModel language, also distributed by SAS, and the input format MPS can also be used for LPs. The optimization routines include solvers for LPs, QPs, NLPs, and mixed-integer problems. There are three options for solving LPs: primal simplex, dual simplex, and interior-point methods. We will focus on the interior-point method here.

SAS/OR incorporates an infeasible primal-dual interior-point method, as described in Ref. 24 and uses Mehrotra's [26]

predictor–corrector framework. A presolve routine is used to check for and remove redundancies, handle singleton rows and columns, eliminate fixed variables, and reduce problem size. The minimum degree heuristic is used for symbolic Cholesky factorization. For numerical factorization, the left-looking, or pull, Cholesky [49], where an iteration consists of a particular column receiving all its updates from all applicable columns to the left, is used.

Xpress Optimizer

Xpress Optimizer [17] is a commercial solver for LP and QPs, distributed as a part of the Xpress-MP suite by FICO/Dash Optimization. It can be used via Console Xpress, which is the graphical user interface of the suite, or as a callable library with C, C++, Java, Fortran, VB6, and .NET programming interfaces. It accepts models written in MPS and LP input formats and can also be called from AMPL or GAMS. Another tool from the Xpress-MP suite, Xpress-Mosel, can be used to take advantage of the object-oriented construction for building advanced models. Xpress Optimizer, as well as the other tools of Xpress-MP, are available for use over the NEOS Server [22]. There is also a parallel implementation. There are three solvers implemented in the Xpress Optimizer: primal simplex, dual simplex, and a barrier interior-point method. We will focus on the interior-point method here.

Xpress Optimizer implements the homogeneous self-dual algorithm described in Ref. 45 and uses Mehrotra’s predictor–corrector framework [26] with Gondzio’s higher-order corrections [27]. A presolve stage determines redundant constraints and may tighten variable bounds as necessary. By default, the code determines whether to solve the primal or the dual LP using the barrier method. For sparse Cholesky factorization, the user can choose among three options for finding an ordering: minimum degree, minimum local fill, or nested dissection. For the numerical factorization, they are given a choice between pull Cholesky, where an iteration consists of a particular column receiving all its updates from all other applicable columns to the left,

and push Cholesky, where an iteration consists of a particular column performing all its updates on all other applicable columns to the right. The default is to use the pull Cholesky.

CONCLUSION

We have presented an overview of available interior-point codes for LP. This list is not exhaustive, as there are numerous codes for conic optimization, such as SDPT3 and SeDuMi, and for nonlinear optimization, such as IPOPT and KNITRO, for which LP problems constitute a special case. We have chosen to focus here on solvers that are either primarily for LP (and by natural extension, QP) or have special features for handling LPs.

Many of the solvers share common features. For example, the use of the predictor–corrector framework and even higher order corrections is quite common, and most solvers implement a minimum degree ordering or a close variation for symbolic Cholesky factorization. The presolve phase also plays an important role, and many of the solvers balance the loss of computing time during presolve with possible gains in efficiency and numerical stability.

INTRODUCTION TO BRANCHING PROCESSES

PETER JAGERS
Department of Mathematical
Sciences, Chalmers
University of Technology
and University of
Gothenburg, Gothenburg,
Sweden

BACKGROUND

Branching processes describe sets of individuals (populations) evolving over time, their size and composition changing by members generating new individuals (giving birth), and possibly disappearing (dying). Thus, they form the basic stochastic model for biological population dynamics, including demography. They can, however, also be used to describe other phenomena where the same pattern occurs, like in nuclear physics, molecular replication, or the performance of a certain computer algorithm.

There are branching processes of varying complexity. In the simple Galton–Watson process, real time is replaced by generation counting: individuals of one generation individually and independently give birth to a number of new individuals according to the same offspring number distribution. These then form the next generation. Another simple form is known as the birth-and-death process (see *Birth-and-Death Processes*). Here time is real, but there is no aging of individuals and reproduction is reduced to binary splitting, or death without children.

On the other end of the spectrum, are general branching processes, where individuals can be of various types, life spans follow arbitrary, type-dependent distributions and births occur as general point processes (see *Introduction to Point Processes*) during life, that is, in any random pattern. These can also be dependent upon the

mother's type, and children can have new types. In classical theory, individuals are still supposed to reproduce asexually and otherwise independently of one another. Recent work has dealt with population size dependence, so that small populations for instance, could reproduce more than big populations do.

Historically, branching processes were born out of the so-called *extinction paradox*; that is, the fact that a rapid growth of a population as a whole does not exclude frequent extinction of separate family lines. This seems first to have been noticed in a human context, as the family (name) extinction problem, by Malthus and a circle of French demographers. (In the fight for survival in biological evolution, extinction is even more prevalent, but we are not considering extinction as a consequence of competition.) The first mathematical treatment seems to be due to I. J. Bienaymé (1845), and later by F. Galton and H. Watson (1873, 1875), who however were led to conclude that all families must die out, even if reproduction is supercritical, that is, the mean offspring number per individual exceeds one. In spite of the implausibility of this result, and a certain controversy about it at the time, it was corrected only half a century later, by Haldane (1927) and definitely, by Steffensen (1930).

The correct extinction theorem reads: Consider a single-type branching process, that is a population where individuals reproduce independently and according to one distribution. If the mean offspring number per individual, m , is less than or equal to one, then the population must die out, while if $m > 1$ there is a positive chance of survival. The extinction probability q for a population with one ancestor is the smallest nonnegative root of the equation $f(q) = q$, where f is the probability generating function of the offspring number distribution. Thus formulated, the theorem is valid not only for Galton–Watson processes but for quite general branching processes. Properly rephrased, it even extends to multitype processes.

The source of confusion was probably that for natural populations, the reproduction law often has both a big mean m and a comparatively large extinction probability q , due to high probability of begetting no children combined with a strong convexity of the reproduction-generating function f .

Another source of inspiration for branching process theory is the growth of populations and the ensuing stabilization of composition. Here, theory goes back to Euler, and many contributions were formulated in the late nineteenth and early twentieth centuries by demographers and actuaries, mostly in a deterministic framework. The exponential rate of free population growth, ascribed to Malthus, is a fundamental result, another is the stable age distribution, in its first version due to Euler himself.

The extinction problem can be formulated in terms of simple branching processes, whereas the growth rates and composition matters can only be meaningfully resolved within models with more realistic time structure. In the case of large populations, the need for a stochastic formulation of individual behavior is also not so clear and as a consequence, it is only rather recently that branching process theory has come to embrace demographic theory and deterministic, so-called structured population dynamics. When it comes to population size dependence and other interplay between environment and individual reproduction, only simple special cases have been treated.

GALTON–WATSON PROCESSES

A (*Bienaymé*–)Galton–Watson or simple branching process $\{Z_n, n = 0, 1, \dots\}$, where Z_n stands for the size of the n th generation, is usually defined from an array of independent, identically distributed non-negative integer-valued random variables $\{X_{ni}; n, i = 1, 2, \dots\}$, with the interpretation of X_{ni} being the number of children of the i th individual of the n th generation, and a starting value Z_0 , conventionally taken as 1, unless something else is mentioned. The technical definition is then recursive

$$Z_{n+1} = \sum_{i=1}^{Z_n} X_{ni}, n = 0, 1, 2, \dots$$

The idea is either that time is disregarded and only generations counted, or else that the scheme should depict the evolution of seasonal populations, say with a life span of one year, like for many plants or insects. Processes are referred to as *supercritical* if the reproduction mean $m = E[X_{ni}] > 1$, critical if $m = 1$, and subcritical otherwise. The *reproduction law* is usually denoted $p_k = P(X_{ni} = k), k = 0, 1, 2, \dots$, so that $m = \sum k p_k$, and the reproduction-generating function, referred to in the previous section is $f(s) = \sum s^k p_k, 0 \leq s \leq 1$.

The most important problem naturally solved within this context is the extinction problem, already mentioned, where a finer time structure is irrelevant. Simple branching processes, however, also serve as a touchstone of results for more refined models. Beyond the extinction theorem, the following basic facts have been proved and in principle, extend to more general forms of branching processes:

1. Exponential growth: If a process does not die out, then it grows like m^n , if and only if there is a finite logarithmic moment of reproduction: $E[X_{ni} \log X_{ni}] < \infty$, the so-called $x \log x$ condition.
2. In a subcritical process, the survival probability decreases like m^n , again under the $x \log x$ condition. Given that the population has not died out, its size stabilizes.
3. In a critical process with finite reproduction variance, $\sigma^2 = \text{Var}[X_{ni}] < \infty$, the survival probability decreases like $2/n\sigma^2$. Conditionally upon nonextinction, critical populations grow linearly.

SPECIAL GALTON–WATSON PROCESSES, GENERALIZATIONS, RAMIFICATIONS

The case of *binary splitting* is of special biological interest, $p = p_2 = 1 - p_0$, occurring in

cells and bacteria. Then obviously $m = 2p$. A variation takes place in molecular replication, where the molecule remains, if it does not double: $p = p_2 = 1 - p_1$ [1].

Various forms of *linear fractional* reproduction can be easily studied and thus command more of purely mathematical interest. The reason is that here the chief analytical tool, reproduction-generating functions, can be explicitly iterated and thus, the behavior of $\{Z_n\}$ often easily found. The reproduction probabilities have the geometric form $p_0 = 1 - a, p_k = ab^{k-1}(1 - b), 0 \leq a \leq 1, 0 \leq b < 1, k = 1, 2, \dots$, yielding generating functions of precisely a linear fractional form. Studies of these processes can give hints about more general or scientifically more relevant branching processes.

Generalizations include *branching processes with immigration* and branching processes in *random environments*. In the former, an immigration component is added to the children of the preceding generation so that the recursion runs like

$$Y_{n+1} = \sum_{i=1}^{Y_n} X_{ni} + I_n,$$

the last variable being the immigration, usually assumed independently and identically distributed (i.i.d.).

Random environments were initially thought to cover cases like weather fluctuations, the mathematical formalization then being that first there is an independent choice of reproduction law, then all reproductions occur in an i.i.d. fashion according to that. Gradually, they have developed into other forms, one of special interest being the case where the environment in which individuals multiply is influenced by the population size itself. In this way, processes can be constructed which are supercritical under and subcritical above a critical population size, in ecology often referred to as the *carrying capacity*.

Interestingly, such processes retain the basic branching process property of either dying out or growing beyond limits. Indeed, the dichotomy between extinction and explosion, that is the impossibility of population size ultimately stabilizing, is an inherent

property of population models that allow leeway for individual variation in reproduction [2, p. 108]. However, population size dependence can give rise to interesting phenomena like *quasi-stationarity*, the time to extinction including a long-time (exponential in the carrying capacity) plateau of oscillation around it. Binary models for molecular replication that include Michaelis–Menten type population size dependence of the replication success probability lead to linear growth of the type observed in experiments, rather than classical exponential growth [2, p. 231].

In the Galton–Watson context of nonoverlapping generations, processes with two sexes and mating have also been investigated, often under the heading of *bisexual* branching processes.

MULTITYPE BRANCHING PROCESSES IN DISCRETE TIME

If mating were not required, but females could reproduce independently, getting both daughters and sons, the latter being sterile, this would provide an example of two-type branching. More generally, *multitype* Galton–Watson processes can be formulated by replacing the random variables X_{ni} by vectors, giving the numbers of children of various types. The X_{ni} are still thought of as independent, but their distributions may be influenced by the mother's type. For further reading refer article titled this encyclopedia or Ref. 3. There is also a theory of general type spaces, the case of discrete time with nonoverlapping generations to be found in Ref. 4, general theory being touched upon in Ref. 2, where further references are also provided.

If types communicate in the sense that an individual of any type can have progeny of any other type, much of single-type theory carries over. The mean matrix $M = \{m_{ij}\}$, where the elements give the expected number of j -children to an i -individual plays a crucial role, and its largest eigenvalue determines the criticality properties of the process.

In genetics, processes where types do not communicate, but fresh types can arise out of

mutation, are of great interest. An extreme version of this is the infinite-alleles model, where all mutations introduce new alleles. Another is provided by branching processes with immigration, where the immigration can be viewed as progeny from a type that besides this progeny, always gets one child of its own type.

AGE-DEPENDENT AND GENERAL BRANCHING PROCESSES

The simplest type of branching processes in continuous time, are known as *birth-and-death* processes. Here, the idea is that individuals give birth at a constant rate λ , at the same time being subject to a constant death risk, μ . This means that the intensity of something, whatever it is, happening in an individual's life is $\lambda + \mu$, and when something happens it is death with probability $\mu/(\lambda + \mu)$ and birth with the complementary probability. An alternative interpretation is therefore, that the individual has an exponentially distributed life span, with parameter $\lambda + \mu$, ended by binary splitting. Since exponential life spans mean that there is no aging, we need not discern between a mother and a newborn.

Birth-and-death processes lend themselves to an immediate generalization *Markov branching processes*: individuals having exponentially distributed life spans end with independent division into a random number of offspring. This is the continuous-time counterpart to Galton–Watson processes, which are discrete-time Markov chains, and results about the latter are readily transferred to continuous time. Sometimes matters are even more easy here [5,6].

Markov branching processes in their turn, lead on to *age-dependent* or *Bellman–Harris* processes. Here, the life span distribution is arbitrary, and the cell or particle is supposed to split into an offspring of random size, independently of the length of life. Thus, the process is age-dependent in the sense that for a Markovian description, ages of all individuals are indispensable. Otherwise, the future development is not well determined, as opposed to the Markov branching case, where

the exponential distribution means that age does not influence future development. On the other hand, reproduction remains independent of the mother's age at death. This was generalized by Sevastyanov into truly age-dependent processes [7].

The next step in the development of branching process theory was the introduction of *general* branching processes, also known under the acronym of CMJ (Crumpp-Mode-Jagers)-processes [2,8]. Here complete generality is achieved, within the frames of independent, asexual reproduction. Individuals can have arbitrary life span distributions, and give birth according to an arbitrary random pattern, very erratically like human females, repeatedly in litters or broods of random size, or splitting like cells or elementary particles. The type space can also be quite general, the reproduction process then taking the form of a marked point process, marks being the types of the newborns.

The extinction or explosion dichotomy persists, and under a generalized $x \log x$ condition, the population exhibits exponential growth, at a so-called *Malthusian rate* if it is supercritical, and the survival chance decreases at an exponential rate in the subcritical case. Also in the critical case, the basic pattern from simple Galton–Watson processes carries over.

Technically, the analysis of general branching processes is much more involved. Martingales and renewal theory (in multi-type formulations Markov renewal theory, (see **Markov Renewal Function and Markov Renewal-Type Equations**), replace the subtle, elementary analysis of reproduction-generating functions that is crucial in the analysis of Bienaymé–Galton–Watson processes or the differential equations of Markov branching.

The concept of *random characteristics* [2] permits the measuring or counting of populations in a multitude of ways. We can count the population of all those alive, or (mathematically fundamental) all those born, or those below a certain age, or those having a certain ancestry, or progeny, in a certain phase of life, or measure the total body mass or DNA content of the population. Limit

theorems (see *Limit Theorems for Branching Processes*) will then exhibit stable compositions in populations not dying out. A very specific example is the stable age distribution of demography, others are the mitotic index of cell kinetics, and even the phylogeny of a random, typical individual.

This all concerns populations not dying out. Interestingly enough, a branching process known to die out, remains a branching process; that is, individuals remain independent in spite of the global condition of extinction. If the original process was supercritical, the new process will be subcritical, and subcritical general branching processes emerge as the natural model for time and path to extinction of threatened populations.

As the starting number grows, a clear pattern emerges: the time T to extinction behaves proportionally to the logarithm of the starting number minus a constant plus a Gumbel random variable. There is also convergence of the suitably normed population size u -ways to extinction, that is at times $uT, 0 \leq u < 1$ [9].

INTRODUCTION TO DIFFUSION PROCESSES

ARKA P. GHOSH
Department of Statistics,
Iowa State University,
Ames, Iowa

INTRODUCTION

The history of diffusion processes begins with the botanist Brown, who during 1826–1827 observed that grains of pollen suspended in a water display a certain type of erratic motion, which did not fit into any of the contemporary mathematical models [1]. This motion came to be known as the Brownian motion. In 1905, Einstein used physical principles to conduct a mathematical analysis of this motion and Wiener provided a rigorous mathematical foundation for the Brownian motion (hence Brownian motion is also called the *Wiener process*). See ***Brownian Motion and Queueing Applications*** for more details on the Brownian motion. Diffusion processes, in some sense, are generalized versions of the Brownian motion. To fully understand the diffusion process, the reader should be familiar with the concept of stochastic calculus. We begin by introducing stochastic differential equations (SDEs) using heuristic arguments, followed by a brief introduction to stochastic calculus which is used to make the SDE formulation more rigorous. General diffusion process is defined next as a solution to SDEs. Finally, we discuss some major properties of diffusion processes and some common examples of diffusion processes.

PRELIMINARIES

It is common to characterize the evolution of a system through differential equations, which typically describes the rate of change of the system, and in some ways, as functions of other variables (e.g., current value of the

state, other variables etc.). Here, the state of the system can be, for example, the length of a queue in a (deterministic) model: Denoting the length of a queue at time $t \geq 0$ as $q(t)$, one may have the following characterization of the evolution of the queue over time,

$$q(0) = q_0, \frac{d(q(t))}{dt} = \theta(t) q(t), \quad t \geq 0. \quad (1)$$

Here, $\theta(t)$ represents the rate of growth (or “decay”) of the queue-length at time $t \geq 0$, and q_0 is the initial queue-length at time $t = 0$. This “population-growth”-type model is quite common in many applications, and makes perfect sense if the growth parameter is a completely known function. However, in reality it is often not known completely; we may know that the rate function is “approximately” $b(t)$ but it is reasonable to assume that it is subject to some random environmental effects, so that we have

$$\theta(t) = b(t) + \text{“noise”},$$

where we do not know the exact behavior of the noise term, but we know its probability distribution. The following text describes how Equation (1) is dealt with, in the presence of random noise.

Heuristic formulation of SDEs

One usually formulates Equation (1) in this more general version:

$$\frac{dQ(t)}{dt} = b(t, Q(t)) + \sigma(t, Q(t)) \cdot \text{“noise”}, \quad (2)$$

where b and σ are some given functions. For a good model for the “noise” part of the above equation, it is common to use a white-noise type model using the “increments” of the Brownian motion $\{W(t)\}$ (see Section 2.1.6.3). Writing Equation (2) in the increment form, we get that for any $0 = t_0 < t_1 < \dots < t_m = t$,

$$(Q_{k+1} - Q_k) = b(t_k, Q_k)(\Delta t_k) + \sigma(t_k, Q_k)(\Delta W_k), \quad (3)$$

where $Q_j = Q(t_j)$, $\Delta W_j = W(t_{j+1}) - W(t_j)$, $\Delta t_k = t_{j+1} - t_j$. Thus, using Equation (2), we get the following formulation describing the dynamics of the process Q , assuming $Q(0) = q_0$:

$$Q(t) = q_0 + \sum_{k=1}^{m-1} b(t_k, Q_k)(\Delta t_k) + \sum_{k=1}^{m-1} \sigma(t_k, Q_k)(\Delta W_k). \quad (4)$$

Now this formulation depends on the time-discretization, and it would be more acceptable in the limiting form as $\Delta t_k \rightarrow 0$, if the limit on the right hand side exists. This led to the formulation of stochastic integrals (which we describe below) and led to the following equation:

$$Q(t) = q_0 + \int_0^t b(s, Q(s)) ds + \int_0^t \sigma(s, Q(s)) dW(s), \quad (5)$$

Here the last integral is defined as the stochastic integral. The above equation is called the Stochastic Differential Equation (SDE) describing the dynamics of the process Q . In addition to the above “integral form”, one often uses an equivalent “differential form” to describe the dynamics of Equation (5):

$$Q(0) = q_0, \quad dQ(t) = b(t, Q(t)) dt + \sigma(t, Q(t)) dW(t), \quad t \geq 0. \quad (6)$$

A diffusion is the solution to the Equation (5) or (6) described above, when it exists. Below, we give a brief introduction to the stochastic calculus that is used to define the stochastic integral in these equations.

Stochastic Integration

Note that there are two types of integral expressions (involving some stochastic process, say $\{X(s)\}$ and some function $f(\cdot, \cdot)$) in (5),

$$\int_0^t f(s, X(s)) ds, \quad \int_0^t f(s, X(s)) dW(s),$$

where W is a Brownian Motion. In most situations, the first integral can be interpreted simply as the Riemann integral, in the classical way. There are several ways of interpreting the second integral; most of them involve viewing this integral as a suitable limit of the partial sum

$$\sum_{k=1}^m f(t_k, X(t_k)) \Delta W_k,$$

as $\Delta t_j \rightarrow 0$ (here, $\{t_j\}$, Δt_j , W_k is as defined in Equation (3)). This leads to the most widely used version of stochastic integrals, called the *Itô integral* (Refs 1 or 2 for more detail). This is the most common approach to define stochastic integrals, where the function-value at left-end-point of the intervals $[t_j, t_{j+1})$ is used to approximate the integrand. One popular alternative (where the middle point of the interval is used) to this is the *Stratonovich Integral* (2, Chapter 3).

Itô Integrals

Let $f(t, x)$ be a continuous function in t and x , such that

$$\int_0^t E(f^2(u, X(u))) du < \infty.$$

Then the Ito integral of $f(t, X(t))$ with respect to $W(t)$ is defined as

$$\int_0^t f(s, X(s)) dW(s) = \lim_{\Delta_k \rightarrow 0} \sum_k (f(t_{k+1}, X_{k+1}) - f(t_k, X_k)) \Delta W_k, \quad (7)$$

where $\Delta_k = \max_k \Delta t_k$, and the limit is defined in the mean-squared sense (a random variable V is called the “mean square limit” of a sequence $\{V_n\}$ if $\lim_{n \rightarrow \infty} E[(V_n - V)^2] = 0$). For the above definition to make sense, we also need to have that the process X is “adapted” to the filtration generated by the Brownian motion W . In simple words, if $\mathcal{F}_t$ denotes the sigma-algebra generated by $\{W(s) : s \leq t\}$ (it contains all the information of W -process till the time t), then $X(t)$ has to be measurable with respect to $\mathcal{F}_t$, for all $t \geq 0$, that is, $X(t)$ can be completely determined using the knowledge of $W(s)$ for $s \leq t$.

DIFFUSION PROCESS

As defined earlier (Eqs 5–6), a diffusion process $\{X(t)\}$ is a solution to the following equation:

$$X(t) = x_0 + \int_0^t b(s, X(s)) ds + \int_0^t \sigma(s, X(s)) dW(s), \quad (8)$$

or, equivalently, to

$$X(0) = x_0, \quad dX(t) = b(t, X(t)) dt + \sigma(t, X(t)) dW(t), \quad (9)$$

where $b(t, x)$ and $\sigma(t, x)$ are continuous functions of t and x , such that

$$\int_0^t E(\sigma^2(s, X(s))) ds < \infty.$$

Here, $b(\cdot, \cdot)$ is called its drift function, and $\sigma(\cdot, \cdot)$ the diffusion function. Here b and σ can be thought of as the infinitesimal mean and variance of the increments of the process X (see **Brownian Motion and Queueing Applications** for more details).

First note that a diffusion process is defined as a solution to a (stochastic differential) equation, and we have to discuss the conditions under which the solution exists. But at this point, it is easy to consider some very basic examples:

Example 1. Setting $x_0 = 0$, $b(t, x) = 0$ and $\sigma(t, x) = 1$ yields that $X(t) = W(t)$, the standard Brownian motion starting at the origin. Similarly, for constant coefficients $b(x, t) = b$, $\sigma(x, t) = \sigma$ yields a Brownian motion with drift b , diffusion parameter σ . So, diffusion processes are more general than the Brownian motion processes described in section 2.1.6.3.

The following result gives a general set of conditions under which diffusion exists (i.e., there is a solution for the SDE in Eq. 8):

Existence Conditions for Diffusion Processes

Let $T > 0$ and $b(\cdot, \cdot), \sigma(\cdot, \cdot)$ be measurable functions satisfying for all real x , and for all $t \in [0, T]$

$$|b(t, x)| + |\sigma(t, x)| < C(1 + |x|), \quad \text{and} \\ |b(t, x) - b(t, y)| + |\sigma(t, x) - \sigma(t, y)| < D|x - y|,$$

for some constants $C > 0, D > 0$, then there exists solution of the SDE in Equation (8). In addition, this solution is also unique. Under much weaker conditions (e.g., continuity of b and σ are strictly nonnegative), one gets uniqueness in the sense that any two solutions will have the same probability distribution (“weak” uniqueness). See Chapter 5.2 of Ref. 2 for more discussion on this.

Example 1 describes one of the simplest types of such processes and now we know conditions under which other diffusion processes exist. Now, suppose $X(t)$ is a diffusion process and $Z(t) = g(X(t))$ for a “nice” function $g(\cdot)$. Can we characterize the dynamics of such a process $\{Z(t)\}$? The answer is provided by the celebrated *Itô’s formula* described below:

Itô’s Formula

Let $\{X(t)\}$ be a diffusion process (i.e., a solution of Eq. 8). Let $g(t, x)$ be a function that is continuously differentiable in t and twice continuously differentiable in x . The stochastic process defined as $Z(t) = g(t, X(t))$ satisfies the following stochastic integral equation:

$$Z(t) = Z(0) + \int_0^t (g_t(s, X(s)) + b(s, X(s))g_x(s, X(s)) + \frac{1}{2}\sigma^2(s, X(s))g_{xx}(s, X(s))) ds + \int_0^t \sigma(s, X(s))g_x(s, X(s)) dW(s), \quad (10)$$

or, equivalently, the stochastic differential equation

$$\begin{aligned}
Z(0) &= g(0, x), \\
dZ(t) &= \left(g_t(t, X(t)) + b(t, X(t))g_x(t, X(t)) \right. \\
&\quad \left. + \frac{1}{2}\sigma^2(t, X(t))g_{xx}(t, X(t)) \right) dt \\
&\quad + \sigma(t, X(t))g_x(t, X(t)) dW(t). \quad (11)
\end{aligned}$$

Here g_t, g_x denote the partial derivatives of g with respect to t and x , respectively and g_{xx} is the second order partial derivative with respect to x .

The above formula is extremely important for dealing with diffusion processes and getting explicit solutions for them (by solving the defining SDEs as in Eq. 8). The following give some applications of this formula, as well as some standard examples of diffusion processes.

EXAMPLES

In Example 1, we already saw that Brownian motion is a simple example of a diffusion process. Here we discuss a few more standard examples.

Example 2 [Geometric Brownian Motion Process]. Recall the motivating example at the beginning of this section (Eq. 2). In this situation, a queue-length process is modeled as the following diffusion process:

$$Q(0) = q_0, \quad dQ(t) = bQ(t)dt + \sigma Q(t)dW(t), \quad (12)$$

where b and $\sigma > 0$ are constants. To solve the above SDE, first we write it as follows:

$$\frac{dQ(t)}{Q(t)} = b dt + \sigma dW(t). \quad (13)$$

Next, applying Itô's formula with $g(t, x) = \ln(x)$ to the diffusion Q described in Equation (12), we get (after simplification) that

$$d\ln(Q(t)) = \frac{dQ(t)}{Q(t)} - \frac{1}{2}\sigma^2 dt. \quad (14)$$

Using Equation (13) and (14), we get that

$$b dt + \sigma dW(t) = d\ln(Q(t)) - \frac{1}{2}\sigma^2 dt,$$

and hence, together with the fact that $Q(0) = q_0$, we have that

$$Q(t) = q_0 \exp\left(\left(b - \sigma^2/2\right)t + \sigma W(t)\right).$$

This is the explicit expression of the diffusion process (implicitly) defined in Equation (12). This diffusion process is known as the *Geometric Brownian Motion process* with parameters b and σ .

Example 3 [Ornstein-Uhlenbeck (OU) Process]. This is another common diffusion process defined by

$$X(0) = x, \quad dX(t) = -bX(t)dt + \sigma dW(t), \quad (15)$$

where $b > 0$ and $\sigma > 0$ are constants (here, b and σ are called the parameters of the OU process). One can show using calculations similar to the ones above that the explicit expression of this diffusion process is as follows:

$$X(t) = \exp(-bt) \left(x + \sigma \int_0^t \exp(bs) dW(s) \right). \quad (16)$$

As we mentioned earlier, diffusion equations are extremely important in operations research, especially in the context of modeling queues, storage processes and so on. In continuous-time models, it is often natural to use discrete-state processes (such as DTMC models in the section titled “Definition and Examples of CTMCs” in this encyclopedia), because of discrete nature of the state-space (e.g., number of people in the queue). However, under suitable scalings (“diffusion”-scaling), the discrete-state system can be approximated by a suitable diffusion. Often the physical models have natural constraints (such as queue-lengths being nonnegative) which lead to constrained diffusions. Since there is a large literature on analysis of the diffusion processes, understanding the approximate system (driven by diffusions) is often possible and usually provides useful insights for the discrete-state physical systems. We provide a list of references below for further reading on these topics.

FURTHER READING

More detail about diffusion processes can be found in classical textbooks on probability, such as Ref. 3. For more recent developments, we encourage the reader to consult Refs 4–7 (incomplete list). For students and researchers learning from this material for the first time, some more accessible texts would be Refs 1 and 2. In many situations, diffusions are Markov processes and hence mathematical tools for Markov processes can be used for diffusions. A reference for general Markov processes would be Ref. 8.

Diffusion processes are often used in physics [9], financial applications [10,11] and many other disciplines. For operations research applications, a general reference would be Ref. 12. For more detailed reference for diffusion processes in queueing theory models, we recommend Refs 13–15.

INTRODUCTION TO DISCRETE-EVENT SIMULATION

RICKI G. INGALLS
School of Industrial Engineering
and Management, Oklahoma
State University, Stillwater,
Oklahoma

DEFINITION OF SIMULATION

Simulation, according to Shannon [1], is “the process of designing a model of a real system and conducting experiments with this model for the purpose either of understanding the behavior of the system or of evaluating various strategies (within the limits imposed by a criterion or set of criteria) for the operation of the system.” According to this definition, a simulation can be a discrete-event simulation, as we will discuss in this article. Many people are familiar with the term “MRP simulation.” This is a model (actually a copy) of the real system (the MRP system of record) on which experiments (or scenarios) can be run to evaluate various strategies (such as how to respond to a drastic change in the forecast). Although we do not teach courses in our curriculum on “MRP simulation,” an MRP simulation is no less a simulation than the type of simulation we will discuss in this article.

The difference, and the power, of discrete-event simulation is the ability to mimic the *dynamics* of a real system. Many models, including high-powered optimization models, cannot take into account the dynamics of a real system. It is the ability to mimic the dynamics of the real system that gives discrete-event simulation its structure, its function, and its unique way to analyze results. So, to take liberties with one of my mentors in this field, we will say that simulation is the process of designing a *dynamic*

model of an actual *dynamic* system for the purpose either of understanding the behavior of the system or of evaluating various strategies (within the limits imposed by a criterion or set of criteria) for the operation of the system.

Throughout this article, we reference ideas and thoughts from Shannon [1], Law and Kelton [2], Banks *et al.* [3], and Kelton *et al.* [4].

A DRIVE-THROUGH EXAMPLE

In order to give us a reference model for discussion purposes, let us consider the example of a drive-through window at a fast-food restaurant whose logic is shown in Fig. 1. As a car enters from the street, the driver, who we call Fred, decides whether or not to get in line. If Fred decides to leave the restaurant, he leaves as a dissatisfied customer. One of the great things about a simulation is that it is easy to track these type of customers. In most real-world systems, it is usually difficult to track customers who leave dissatisfied.

If Fred decides to get in line, then he waits until the menu board (with the speaker no normal human being can understand) is available. At that time, Fred gives the order to the order taker.

After the order is taken, two things occur simultaneously: (i) Fred moves forward if there is room. If there is no room, then he has to wait at the menu board until there is room to move forward. As soon as there is room, he moves so the next customer can order. (ii) The order is sent electronically back to the kitchen where it is prepared as soon as the cook is available.

As soon as Fred reaches the pickup window, he pays and picks up his food, if it is ready. If the food is not ready, then Fred has to wait until his order is prepared. In this drive-through, Fred never hears, “Please pull forward and we will bring your order out

Figure 1. Drive-through example logic flow.

to you.” That is one of the reasons that Fred and I both like this place.

As soon as Fred parts with his money and gets his food, he leaves the pickup window as a satisfied customer.

DISCRETE-EVENT SIMULATION STRUCTURE

Although there are various flavors and paradigms in discrete-event simulation, there has evolved a basic structure that is

used by most simulation packages. Regardless of how complex a discrete-event simulation package may be, it is likely to contain the basic components that we describe in this section.

The structural components of a discrete-event simulation include *entities*, *activities and events*, *resources*, *global variables*, a *random number generator*, a *calendar*, *system state variables*, and *statistics collectors*.

Entities

The best way to understand the function of an entity is to understand that *entities cause changes in the state of the simulation*. Without entities, nothing would happen in a simulation. As a matter of fact, one stopping condition for a simulation model is the condition where there are no active entities in the system.

Entities have *attributes*. Attributes are characteristics of a given entity that are unique to that entity. Attributes are critical to the understanding of the performance and function of entities in the simulation.

In our example, the primary entity type is the cars coming to the restaurant. Also, there is a second entity type created when the order is taken, and that is the order itself. It has a relatively short life in the simulation, lasting only from the time the order is taken until it meets back up with the car at the pickup window.

We also have two attributes in our simulation. The first one is the time of day that the car enters the restaurant parking lot. We call this attribute *StartTime*. The second is the value of the order. We call this attribute *OrderValue*. Both these are unique to the customers who are represented in the simulation.

Another example of an entity is a part that is flowing through a factory. Entities that represent parts in a factory could be created randomly or according to a schedule. A common attribute would be the time that the part started in the factory. Each part would have a unique time that it started in the factory. It may also have other attributes such as priority, the type of part, and the cost incurred to produce the part. In a normal

factory simulation that is tracking each individual part, it would not be unusual to have thousands of entities active in the simulation simultaneously.

Entities, however, do not need to be parts in a manufacturing facility or cars in a drive-through. It is also a common practice to use entities to represent the flow of *information*. This information could be a customer order, an e-mail alert, a packet in a computer network, and so on. It can be anything nonphysical that causes a change in the status of the system. These entities also have attributes. For example, an entity representing a packet in a computer network would have attributes such as packet size, packet destination, the time that the packet would time-out, and so on.

Activities and Events

Activities are processes and logic in the simulation. *Events* are conditions that occur at a point in time which cause a change in the state of the system. An entity *interacts* with activities. Entities *interacting with* activities *create* events.

There are three major types of activities in a simulation: *delays*, *queues*, and *logic*. The *delay* activity is when the entity is delayed for a definite period of time. In our example, there are three delays. The first is when Fred is ordering at the menu board, the second is when the order is being cooked in the kitchen, and the third is when Fred picks up his order at the pickup window. In general, the length of time of a delay is either constant or is randomly generated. At the point that the entity starts the delay, an event occurs. This event schedules the entity on the *calendar* (which we will get to later). If the delay is for d time units, then the entity is scheduled to complete the delay d time units after the current time of the simulation. At that time, the delay expires and another event is generated.

Queues are places in the simulation where entities wait for an unspecified period of time. Entities can be waiting on *resources* (which we will get to later) to be available or for a given system condition to occur. *Queues* are most commonly used for waiting in line for a resource or storing material that will be taken out of the queue when the right

conditions exist. In our example, there are three queues: the first is the part of the line that waits on the menu board to be available, the second is the order waiting on the kitchen becoming available, and the third is the part of the car line waiting on the order pickup window to become available. All three of these queues are waiting for *resources* to be available.

Logic activities simply allow the entity to effect the state of the system through the manipulation of state variables (which we get to later) or decision logic. The first of several logic activities in our example is the decision whether to get in the order line in the first place. This decision is effected by the length of the line in front of the menu board.

Resources

In a simulation, resources represent anything that has a restricted (or constrained) capacity. Common examples of resources include workers, machines, nodes in a communication network, traffic intersections, and so on. In our example, we have three different resources. The first resource is the menu board, which only one car can use at a time. The menu board is utilized from the time a car moves in front of it until the car moves away from it. In our model, the car does not automatically move away from the menu board after the order has been placed. There must also be room to move forward. So, this resource is occupied for both productive time (when the order is being placed) and unproductive time (when there is not enough room to pull the car forward). The second resource is the kitchen. It is utilized from the time an order arrives until the order is finished cooking. The third resource is the order pickup window. This resource can also be unproductive. That occurs when the car has arrived at the window, but the order is not ready from the kitchen yet. In the course of the simulation, we can track the key statistics of each of these resources, including utilization and costs.

It should also be noted that very complex resources can be utilized in a simulation. In a manufacturing simulation, conveyors are a very complex resource that many simulation packages offer. Also, transportation options

such as trucks are offered as resources. A third complex resource is a vat or container that has a (continuous) flow of material both in and out of the resource. Depending on the target market of the simulation package, many complex resources are available for use.

Global Variables

If you are a programmer, then the idea of having *global variables* is nothing new. A *global variable* is a variable that is available to the entire model at all times. A global variable can track just about anything that is of interest to the entire simulation. In our model, we have four global variables, two of which help us configure the problem and two of which collect revenue information. The two variables that help us configure the problem are the length of the line allowed at the restaurant. The first is *MenuBoardLineSize*, which gives the maximum line size for the menu board, including the car that is at the menu board. The second is *OrderPickupLineSize*, which gives the maximum line size after the menu board, including the car at the pickup window. By changing these two variables, the simulator can analyze the effectiveness of different line configurations.

The two variables that help use collect revenue information are *Revenue* and *LostRevenue*. *Revenue* is the total amount of revenue collected in the simulation, and *LostRevenue* is the total amount of revenue lost because the customer thought that the line was too long.

Random Number Generator

Every simulation package has a random number generator. The random number generator (technically called a *pseudo-random number* generator) is a software routine that generates a random number between 0 and 1 that is used in sampling random distributions. For example, let us assume that one has determined that a given process delay is uniformly distributed between 10 min and 20 min. Then every time an entity went through that process, the random number generator would generate a number between 0 and 1 and evaluate the uniform distribution formula that has a

Figure 2. Distribution of rolling two dice.

minimum of 10 and a maximum of 20. As an example, let us assume that the generated random number is 0.7312, then the delay would be $10 + (0.7312) \times (20 - 10) = 17.312$. So, the entity would delay for 17.312 time units in the simulation. Everything that is random in the simulation uses the random number generator as an input to determine values.

In our example model, we will use a physical random number generator, two dice. The probability distribution for the roll of two dice is seen in Fig. 2. In our model, the roll of two dice becomes the basis for every random delay and randomly assigned value in the model. We have five randomly assigned delays and values in the model: (i) the time between arrivals of cars to the restaurant, (ii) the value of the order for the car, (iii) the delay at the menu board, (iv) the delay at the kitchen, and (v) the delay at the order pickup window. The formulas for these random values are as follows:

1. Time between arrivals of cars to the restaurant = $(\text{Dice} \times 10)$ (s).
2. The value of the order for the car = $(\text{Dice} \times 2) - 2$ (\$).
3. The delay at the menu board = $(\text{Dice} \times 10)$ (s).
4. The delay at the kitchen = $(\text{Dice} \times 8)$ (s).
5. The delay at the order pickup window = $(\text{Dice} \times 10)$ (s).

The Calendar

The *calendar* for the simulation is a list of events that are scheduled to occur in the future. In every simulation, there is only one calendar of future events and it is ordered by the earliest scheduled time first. In a later example, it will become clearer how the calendar works and why it is important in the simulation. At this point, just remember that, at any given point in time, every event that has already been scheduled to occur in the future is held on the calendar.

System State Variables

Depending on the simulation package, there can be several system state variables, but the system state variable that every simulation package has is the current time of the simulation. In order to keep from offending any simulation vendors, we choose a different name for our simulation time variable. Our name of the current time of the simulation is *CurrentTime*. This variable is updated every time an entity is taken from the calendar.

Statistics Collectors

Statistics collectors are a part of the simulation that collect statistics on certain states (such as the state of a resource), or the value of global variables, or certain performance statistics based on attributes of the entity. There are three different types of statistics

that are collected: *counts*, *time-persistent*, and *tallies*. Counts are very straightforward, they *count*. In our model, we count the number of *Lost Customers* because the line was too long. *Time-persistent* statistical collectors give the time-weighted values of different variables in the simulation. A common variable to track is the utilization of a resource. In our model, we collect six different time-persistent statistics, which are the number of busy resources of the three resources that we have in the model and the number of entities in each of the three queues that serve the three resources. *Tally statistics* are collected one observation at a time without regard to the amount of time between observations. In our model, we collect a very common statistic, which is the amount of time that an entity stays in the system. Since we assign the value of *StartTime* to the attribute of the entity when it enters the restaurant parking lot, then the value $CurrentTime - StartTime$ is the total amount of time in the system. If we are to improve this system, we would want to minimize this statistic without hurting the revenue too much.

A WALK THROUGH THESE CONCEPTS

What we are going to do now is walk through a couple of steps in our simulation model. As one can see later, we track the state of the system, the entities on the calendar, the

values of attributes and state variables, and the statistics we are collecting.

The State of the System at Noon

Figure 3 shows the state of the system at noon during a lunch rush at our fast-food restaurant. To help us design the line at the restaurant, we have set two of our global variables, *MenuBoardLineSize* and *Order-PickupLineSize*, both equal to 3. As one can see, it is the total capacity of the line at the restaurant. The state of our system at noon is as follows:

- Car 1 (the Corvette) is at the Order Pickup Window receiving its order.
- Cars 2 (the convertible VW Bug) and 3 (the minivan) are in line waiting for the Order Pickup Window.
- Car 4 (the 2-seat convertible) is ordering at the Menu Board.
- Cars 5 (the Police Car) and 6 (the Porsche) are waiting in line for the Menu Board.
- The Order for Car 2 is being cooked in the Kitchen.
- The Order for Car 3 is waiting in line for the Kitchen.
- Car 7 (of undetermined type) is scheduled to arrive at the restaurant in the future.

Figure 3. State of the system at noon.

Table 1. The Calendar at Noon

Entity	Event	Event Time
Car(7)	Arrive at restaurant	12:00:20 p.m.
Car(1)	Order pickup window complete	12:00:40 p.m.
Order(2)	Kitchen complete	12:00:56 p.m.
Car(4)	Menu board complete	12:01:10 p.m.

The calendar of this system is made up of the entities that are scheduled to complete an activity with a specific time duration. These entities are Car 1, Car 4, the Order for Car 2, and Car 7. The calendar for these four entities is shown in Table 1.

We also know the values of the attributes of the entities in the system. As you recall, we have two attributes, *StartTime* and *OrderValue*. The values for those attributes for each of the entities in the system is outlined in Table 2.

Other important information concerns our system state variable, *CurrentTime*, which is set to 12:00:00 p.m.

The statistics that we are tracking in the simulation have the values listed in Table 3 as of noon. The “Time/Obs” column gives the amount of time that we have been collecting the statistic (which is since 11:00 a.m.) for time-persistent statistics or the number of observations for tally statistics.

The State of the System at 12:00:20 p.m.

Here is where we get one of the key ideas about a *discrete-event simulation*. A discrete-event simulation moves the current time of the simulation through events and their timing instead of distinct time intervals. If we had distinct time intervals of 1 s, we would go through 20 time intervals before anything would happen. So instead

Table 2. Entity Attributes at Noon

Entity	<i>StartTime</i>	<i>OrderValue</i> (\$)
Car(1)	11:54:20 a.m.	10
Car(2)	11:55:50 a.m.	6
Car(3)	11:57:10 a.m.	4
Car(4)	11:58:20 a.m.	14
Car(5)	11:59:30 a.m.	14
Car(6)	12:00:00 p.m.	10
Car(7)	—	—

Table 3. Statistics at Noon

Statistic	Value	Time/Obs
Revenue	\$504	—
Lost revenue	\$74	—
MenuBoard utilization	0.9984	1:00:00
Kitchen utilization	0.7006	1:00:00
OrderWindow utilization	0.9678	1:00:00
MenuBoard waiting in line	1.2306	1:00:00
Kitchen waiting in line	0.0822	1:00:00
OrderWindow waiting in line	1.0311	1:00:00
Time in system	5.5969	44

of going through 20 time intervals with nothing happening, we go straight to the next scheduled event, which is the first event on the calendar, which is scheduled to occur at 12:00:20 p.m. That event is the arrival of Car 7 to the restaurant.

When Car 7 arrives at the restaurant, the first activity in the simulation is to set its attributes. Obviously, *StartTime* is set to 12:00:20 p.m., and the *OrderValue* is set using the formula $(\text{Dice} \times 2) - 2$ after we roll the dice. The roll of the dice gives us a 9, so the value of the order is \$16. After the attributes are assigned, Car 7 makes a decision whether to get in line to order. Since we have set the *MenuBoardLineSize* = 3 and there are 3 cars in the line, Car 7 leaves as a dissatisfied customer. When Car 7 leaves, we want to capture some important information, namely how much revenue we have lost because of dissatisfied customers, which is tracked in our global variable *RevenueLost*. *RevenueLost* is incremented from \$74 to \$90.

Now that Car 7 has arrived at (and subsequently, left) the restaurant, we also need to schedule the arrival of the next car (Car 8) to the restaurant. The time between arrivals to the restaurant is set using the formula $(\text{Dice} \times 10)$ in seconds. So, we roll the dice and get a 7. Car 8 will arrive 70 s in the future at time 12:01:30 p.m. Car 8 is now put on the calendar with the event “Arrive at Restaurant” that will occur at the event time of 12:01:30 p.m.

So what has changed? Car 7 has arrived and left and Car 8 is scheduled to arrive in the future. We have also updated *RevenueLost*. We have a new calendar, which is shown in Table 4.

Table 4. The Calendar at 12:00:20 p.m

Entity	Event	Event Time
Car(1)	Order pickup window complete	12:00:40 p.m.
Order(2)	Kitchen complete	12:00:56 p.m.
Car(4)	Menu board complete	12:01:10 p.m.
Car(8)	Arrive at restaurant	12:01:30 p.m.

Table 5. Statistics at 12:00:20 PM

Statistic	Value	Time/Obs
Revenue (\$)	504	—
Lost revenue (\$)	90	—
MenuBoard utilization	0.998409	1:00:20
Kitchen utilization	0.702254	1:00:20
OrderWindow utilization	0.967978	1:00:20
MenuBoard waiting in line	1.234851	1:00:20
Kitchen waiting in line	0.087271	1:00:20
OrderWindow waiting in line	1.036453	1:00:20
Time in system	5.5969	44

The statistics can be updated at this point as well. (However, most simulation packages only update statistics when the value that is being tracked changes.) We have two types of statistics, the counting of *Revenue* and *RevenueLost*, the resource utilization statistics and the queue length statistics. The counting statistics is simply the values of the variables we are tracking, and *RevenueLost* has gone to \$90. The other statistics is time-dependent statistics that are time-weighted averages of a given value. As an example, let us calculate the new value of the average number of cars waiting in line for the menu board. At noon, the simulation had been running for 1 h and the average value was 1.2306. From noon to 12:00:20 p.m., the number of cars waiting in line for the menu board has been 2. So the new time-weighted average is $[(1.2306 \times 1:00:00) + (2 \times 0:00:20)]/1:00:20 = 1.234851$. If we were to convert this formula to seconds, it would be $[(1.2306 \times 3600) + (2 \times 20)]/3620 = 1.234851$. All time-dependent statistics are calculated in this way. The value for all of the statistics at time 12:00:20 p.m. is in Table 5.

The State of the System at 12:00:40 p.m.

We want to take one more step in the simulation because we actually see the line move!

Looking at Table 4, we know that the next scheduled event is that Car 1 finishes its time at the Order Pickup Window at time 12:00:40 p.m. The first thing to do is set the *CurrentTime* to 12:00:40 p.m. When Car 1 finishes its time at the Order Pickup Window, we know that Car 1 has paid for its order, and so *Revenue* must be increased by the *OrderValue* attribute of Car 1. So the value *Revenue* is increased from \$504 to \$514. We also need to calculate a new average *Time in System* statistic. The time in the system for Car 1 is the *CurrentTime StartTime*, which would be 12:00:40 p.m. – 11:54:20 a.m., which is 6 min and 20 s. Since we are collecting *Time in System* in minutes, the new average *Time in System* is $[(5.5969 \times 44) + 6.3333]/45 = 5.613265$. The other thing that occurs is that the *Order Pickup Window* resource is no longer utilized. Since the *Order Pickup Window* resources is available for other cars, the simulation will allocate the *Order Pickup Window* resource to the car that is first in the line that is waiting to use the *Order Pickup Window*. Our Car 2 (the convertible VW Bug) is first in line for the *Order Pickup Window*, so Car 2 is allocated the *Order Pickup Window* resource. Can Car 2 start picking up its order? No, it cannot. The reason is that the order for Car 2 is still in the Kitchen. So even though the *Order Pickup Window* resource is occupied, no productive work is going on. At the next step in the simulation, the order for Car 2 will complete in the Kitchen and Car 2 will be able to start the process of picking up its order. But for now, it just has to wait!

Since Car 2 has moved forward, Car 3 moves to first place in the line waiting for the *Order Pickup Window* resource. Car 4 is still occupies the *Menu Board* resource and is still in the process of giving its order. This process is scheduled to end at time 12:01:10 p.m. (See Table 4). Cars 5 and 6 do no change their positions in the line and Car 8 is still scheduled to arrive at the restaurant at time 12:01:30 p.m. The new state of the system is shown in Fig. 4.

We also update our statistics at this time. As we described in at time 12:00:20 p.m., we look at what has happened since the last time we updated the statistics in order to determine the new values for the statistics.

Figure 4. The state of the system at 12:00:40 p.m.

Table 6. Statistics at 12:00:40 p.m

Statistic	Value	Time/Obs
Revenue (\$)	514	—
Lost revenue (\$)	90	—
MenuBoard utilization	0.998418	1:00:40
Kitchen utilization	0.703890	1:00:40
OrderWindow utilization	0.968154	1:00:40
MenuBoard waiting in line	1.239055	1:00:40
Kitchen waiting in line	0.092286	1:00:40
OrderWindow waiting in line	1.041747	1:00:40
Time in system	5.613265	45

So, what number will we use to calculate the new average number of cars waiting for the *Order Window*, 2 (the number in line at 12:00:20) or 1 (the number in line now)? The answer is 2 because from time 12:00:20 p.m. to 12:00:40 p.m. there were 2 cars waiting in line. The new values for the statistics are shown in Table 6.

INTERPRETING OUTPUT STATISTICS

Let us assume that our model has run from 11:00 a.m. to 2:00 p.m. At 2:00 p.m., we stop the simulation and we have all of our statistics calculated. The “answer” for the simulation is in Table 7.

But what does this data really tell us? Is it saying that every day, from 11:00 a.m. to 2:00 p.m., the revenue for the restaurant will be \$1638? Is it saying that every day, from 11:00 a.m. to 2:00 p.m., the average amount

Table 7. Statistics at End of Simulation

Statistic	Value	Time/Obs
Revenue (\$)	638	—
Lost revenue (\$)	170	—
MenuBoard utilization	0.9724	3:00:00
Kitchen utilization	0.7250	3:00:00
OrderWindow utilization	0.9846	3:00:00
MenuBoard waiting in Line	0.8785	3:00:00
Kitchen waiting in line	0.133	3:00:00
OrderWindow waiting in line	1.1567	3:00:00
Time in system	5.0487	140

of time that a car will be in line is 5.0487 min? What is this really saying?

The answer to that question is, “These numbers give us a random answer to the performance of the system.” It is a random answer because there are random inputs to the system that give us this answer. So how can we be sure that the answer is any good?

The answer generated by only one run is not really an answer at all. To make the point, let us take the following 100 rolls of the dice. You would think that 100 rolls of the dice would tell us the average. But if you take the 100 rolls in Table 8, the average is only 6.72. Is that close enough? Would you be willing to bet that the next 100 rolls would come up with an average of 6.72. Probably not. (If you are, please contact me as soon as possible on any other wagers you may be considering.)

So what is the answer to this problem? The answer is that, if we really want to estimate the average value of the roll of the dice if we

Table 8. Rolls of the Dice

6	5	8	6	5	4	10	6	7	8
5	9	8	7	8	6	3	8	7	6
9	9	8	8	6	8	9	7	10	5
2	10	11	8	6	8	7	3	8	8
4	6	8	11	2	4	8	9	8	5
9	3	8	7	2	3	9	10	7	7
3	9	5	7	7	7	9	4	8	7
4	10	7	4	10	8	4	8	9	7
3	6	6	3	6	3	10	9	7	4
6	8	5	9	12	6	8	6	4	2

Average: 6.72.

Table 9. 30 Iterations of Throwing Dice 100 Times

6.72	6.95	6.78	7.14	6.62	6.81
6.75	7.17	6.62	7.3	6.92	7.04
6.79	7.13	7.17	7.12	6.82	7.29
7.13	7.26	7.19	6.52	6.8	7.3
6.95	6.96	6.78	7.17	7.13	6.68

Average: 6.967; standard deviation: 0.22992; 95% confidence interval: [6.8847, 7.0493].

roll the dice 100 times, we need to run the simulation more times. Each time that we run a simulation is called an *iteration*. So, as an example, let us say that we have run our dice-throwing simulation for 30 iterations, and Table 9 has the average values for each of those iterations.

If we are simply trying to estimate the average of 100 rolls of the dice, we do not need to worry about the standard deviation for each iteration. However, we do need to worry about the standard deviation of the averages from each iteration. As is shown in Table 9, the average of the averages (so to speak) is 6.967. The standard deviation of those 30 averages is 0.22992. With that information, we can calculate a *confidence interval*.

A confidence interval is a statistical measure where we want to bound some statistic. The level of confidence (95% in our example) is the statistical probability that the statistic that we are considering lies in the interval. So, the interpretation of the 95% confidence interval of [6.8847, 7.0493] would be “There is a 95% chance that the true average of rolling the dice 100 times lies between 6.8847

Table 10. Confidence Intervals (CIs) after 30 Iterations

Statistic	Value	CI Lower	CI Upper
Revenue (\$)	1649	1627	1670
Lost revenue (\$)	155	135	176
Lost customers	12.83	10.99	14.67
MenuBoard utilization	0.97	0.96	0.98
Kitchen utilization	0.73	0.72	0.74
OrderWindow utilization	0.99	0.99	0.99
MenuBoard waiting in line	0.95	0.89	1.01
Kitchen waiting in line	0.12	0.11	0.13
OrderWindow waiting in line	1.23	1.18	1.28
Time in system	5.31	5.18	5.44

and 7.0493.” Most statistical and simulation packages automatically calculate confidence intervals for you. Even Microsoft Excel has a function to calculate confidence intervals.

So, in our example, we want to run 30 iterations so that we can have good confidence intervals for each of our statistics. (Although we will not get into the topic in this article, one should run 30 iterations (or more if you can) in order to get good confidence intervals.) Table 10 shows the confidence intervals for each of our statistics.

These statistics are very interesting on several fronts. First, we could improve our revenue every day at lunch 9.4% if we could capture the lost revenue. We need to find a way to lower the number of lost customers from the 12.83 that we have seen in the current system. We also know that both the *Menu Board* and *Order Window* are highly utilized, which means that lines are forming in front of those two resources. We would also want to look at reducing the car’s time in the system. The minimum average theoretical time for a car would be 70 s at the *Menu Board* and 70 s at the *Order Window*, which is 140 s, or 2.33 min. So, about 3 min of the car’s time is simply waiting. A key customer satisfaction metric is to minimize the amount of time they have to wait in line.

FINDING WAYS TO IMPROVE A SYSTEM

What we have accomplished to this point is the analysis of a system that exists. We have

learned that we can improve revenue and that we have very busy resources. So let us run some alternative scenarios to determine what (if any) improvements we should make.

Scenario 1: No Lines

Scenario 1 is based on the “eliminating inventory” thought. If we want to get the customer out of the system quicker, we would simply need to eliminate some (or all) of the line. We will take drastic action and eliminate all waiting in the system. If a car cannot pull right up to the *Menu Board*, then it will leave. If the *Order Window* is not available after the order is placed, then the car waits at the *Menu Board* until the *Order Window* is free. This should greatly lower the *Time in System* statistic. Some would say that this would be the best way to run the drive-through line since the system is *balanced*. The arrival rate is 1 every 70 s, the *Menu Board* rate is 1 every 70 s, and the *Order Window* rate is 1 every 70 s. Some would say that this is a perfect production line.

In order to accomplish this in the model, we simply change two variables, *MenuBoardLineSize* and *OrderPickupLineSize*, and set them both to a value of 1. Then we run the model for 30 iterations and get the statistics in Table 11.

Well, the strategy worked the way we expected it to work. We reduced the *Time in System* statistic by 37.7%. Now the cars are whipping through the drive-through. But there is a catch. We are losing 5.5 times

the number of customers that we were losing before! We have lowered our revenues by 40%! This would hardly be considered a viable alternative!

What was it about eliminating the lines that caused such a problem? Without the lines, we caused excessive *blocking* in the system. Blocking occurs when something in the system will not allow a resource to become available even though its service is finished. Throughout this scenario, the car at the *Menu Board* was finished ordering, but the car could not move forward because the *Order Window* was still occupied. In this scenario (or in any balanced system with random variation and no queueing space), each car at the *Menu Board* has a 50% chance of being blocked by the *Order Window*. This can be reduced by adding queues between the resources.

In industrial problems, it is often difficult to determine where and why blocking occurs. That is why there is so much emphasis on eliminating and/or controlling the *bottleneck* of the system. It is likely that the bottleneck is responsible for blocking in other parts of the system.

Scenario 2: Longer Lines at the Menu Board

Well, since Scenario 1 did not work very well, let us try another. Let us rearrange the parking lot so that we can get room for 6 cars waiting in line for the *Menu Board* (including the car whose order is being taken). We will keep the line for three cars for the *Order Pickup Window*. The results for Scenario 2 is shown in Table 12.

Well, we did add revenue (\$51 per day) and decrease the number of lost customers, that is good; but now the average customer waits an additional minute to get the order, which is bad. You can see why this occurs. With the *Menu Board* line being longer, more cars can wait for the menu board and they do not become lost customers in this scenario, where they would have become lost customers in the original model. The price they pay for having room to get in line is that the line is longer, and so the time through the system increases. This is another typical trade-off. Queues are good because they allow more throughput in

Table 11. Scenario 1 Statistics

Statistic	Value	CI Lower	CI Upper

OrderWindow utilization	0.99	0.99	0.99
MenuBoard waiting in line	3.07	2.90	3.24
Kitchen waiting in line	0.13	0.12	0.14
OrderWindow waiting in line	1.28	1.23	1.33
Time in system	6.33	6.14	6.52

a system, but they add cycle time for the system.

Scenario 3: Improved Service Times

Let us try one more scenario. This scenario has found new technology that will cut the average service time at the Menu Board and the Order Window by 20% from 70 s to 56 s. To implement this technology, it would take \$30,000 at each store and must be paid for by increased revenue at the store. This is the only thing that changes from the original model. The results are shown in Table 13.

Well, now we see some improvement! The *Time in System* has dropped from 5.31 min to 3.42 min. We have virtually eliminated any lost customers, and have increased revenue by \$174 per lunch shift. We would pay back

Table 13. Scenario 3 Statistics

Statistic	Value	CI Lower	CI Upper
Revenue (\$)	1822	1794	1850
Lost revenue (\$)	10	5	15
Lost customers	0.70	0.33	1.07
MenuBoard utilization	0.81	0.80	0.82
Kitchen utilization	0.79	0.78	0.80
OrderWindow utilization	0.97	0.97	0.97
MenuBoard waiting in line	0.26	0.23	0.29
Kitchen waiting in line	0.23	0.21	0.25
OrderWindow waiting in line	0.85	0.82	0.88
Time in system	3.42	3.36	3.48

the \$30,000 for the implementation of the new technology in 172 days or less than 6 months! It is well worth the investment and you are a hero for figuring it out!

Why did this scenario show such improvement? It was because our resources were not so highly loaded. The *Menu Board* utilization dropped from 97 to 81%, and so the line for the Menu Board would be much smaller (it dropped by 72%). We would have seen a similar drop in the *Order Window* utilization, but now the Order Window is being often being blocked by the Kitchen.

Generating Other Scenarios

This simulation and any other simulation can be used to evaluate many different scenarios if the person creating the model allows some flexibility in the model structure. One also has to consider the amount of time it takes to run a new scenario. In a large-scale simulation, to run and evaluate a new scenario could take several days.

WHAT HAVE WE LEARNED?

This exercise points out several things about simulation in general. First, simulation can mimic the *dynamic* behavior of a system. That is what it is built to do. Regardless of how complex a system may be, it is likely that a simulation *expert* will be able to create a model that will evaluate it. However, the more complex a system is, the longer it takes to model, run, and evaluate. But do not be discouraged, there are very good simulation people available to model large systems.

Second, you (or the person analyzing the system) must have a good understanding of simulation statistics. It is important during the creation of the model so that input distributions are used properly. It is important during the analysis of the output statistics so that the output is not misinterpreted. Mistakes with either the inputs or the outputs will cause the simulation analysis to be invalid.

Third, to analyze a system, simulation is used to evaluate different scenarios. It does not choose the best scenario for you. This may seem to be a problem, but most managers

have no shortage of scenarios to evaluate. The trade-off for this is that you can analyze the *dynamics* of the system and not just the average behavior.

Fourth, the scenarios that you do choose are generated by you and not the system. This is where familiarity with the system under study and a familiarity with system dynamics concepts are very valuable.

Discrete-event simulation is a complex and powerful tool that you can be used effectively to analyze large systems.

INTRODUCTION TO FACILITY LOCATION

LAWRENCE V. SNYDER
Department of Industrial and
Systems Engineering,
Lehigh University,
Bethlehem, Pennsylvania

Facility location problems involve choosing locations for facilities in order to serve customers while achieving some balance between cost and service. If we open too few facilities, customers will tend to be far from their nearest facility, while if we open too many, infrastructure costs will be large. The facilities may be factories, warehouses, distribution centers, and so on, while customers may represent actual consumers or downstream facilities such as retailers. Many location problems involve two sets of decisions: where to locate, and which customers should be assigned to which facilities. They are therefore sometimes known as *location-allocation problems*.

Facility location is one of the oldest classes of operations research (OR) problems, and the field reflects OR's roots as a multidisciplinary endeavor. Facility location problems are studied by academics and practitioners from economics, mathematics, computer science, geography, and marketing, as well as from OR and its siblings such as industrial engineering and management science. Articles on the subject range in tone from highly theoretical mathematical and algorithmic investigations to highly applied, practical case studies.

Facility location models have been widely applied in both public and private sectors to choose locations for such facilities as emergency medical services (EMS) [1], fire stations [2], airline hubs [3], blood banks [4], fast-food restaurants [5], public swimming pools [6], schools [7], vehicle inspection stations [8], and bus stops [9]. (See Current *et al.* [10] for additional examples). They have been used to locate entities that one would not

normally consider to be facilities, such as wildlife reserves [11], satellite orbits [12], and bank accounts [13]. They have also been applied to problems in which no physical entities are to be located, but the facilities and customers are a modeling construct in order to make other types of decisions, such as tool selection in flexible manufacturing systems [14], platform positioning by political parties [15], and screening tests for cervical cancer [16]. They also sometimes arise as subproblems for other OR problems such as vehicle routing [17].

Since most classical facility location problems are simple to describe and formulate, yet difficult (NP-hard) to solve, they have been a "proving ground" for many optimization algorithms. Nearly every algorithmic method that has been developed for integer programming (IP) problems has, at one time or another, been applied to facility location. These include exact approaches such as branch and bound, branch and cut, and relaxation and decomposition methods, as well as metaheuristics such as genetic algorithms and tabu search.

This article provides a broad overview of the field of facility location (also known as *location theory*, or *location analysis*). The article is not meant to be a complete review of the literature; indeed, such a review would be virtually impossible given the huge number of articles, books, and other references that have been written about the topic. (The online bibliography by Hale [18] cites over 3400 scholarly works.) Many other reviews and surveys of facility location have been written; see Table 1 for a partial list. Textbooks on location theory include those by Handler and Mirchandani [19], Hurter and Martinich [20], Mirchandani and Francis [21], Daskin [22], Drezner [23], Drezner and Hamacher [24], Eiselt and Sandblom [25], and Eiselt and Marianov [26]. Professional society subdivisions devoted to facility location include the INFORMS Section on Location Analysis (SOLA; [27]) and the EURO Working Group on Locational Analysis (EWGLA; [28]).

The section titled “Taxonomy” discusses several dimensions along which location models are often classified. Six classical models, including their mathematical programming formulations and solution methods, are described in the section titled “Classical Models.” The section titled “Extensions” discusses some of the subfields that extend and expand the classical models to richer settings. In general, the focus is on discrete and network location models (see the section titled “Topology”) throughout the article since they are the most commonly studied models.

TAXONOMY

This section discusses some of the most common dimensions along which facility location models are classified.

Topology

Perhaps the most important question in describing a facility location problem is, where may the facilities be located? The answer has important implications on how the problem is formulated, analyzed, and solved. Most problems fall into one of

the following three categories: continuous, network, or discrete problems.

In *continuous* location models, facilities may be located anywhere on the plane (or on some other continuous region). The earliest location problems were of this type. For example, the Weber problem [64] involves choosing the location of a single facility to minimize the total Euclidean distance between the location and a set of fixed customer locations (see the section titled “Classical Models”). A special case of continuous models, known as *analytical* models, assumes that the customers are distributed continuously over some region. (In contrast, in the Weber problem and most other continuous models, the decision space for the facility locations is continuous, but the customers are located at fixed, discrete points.) The goal is generally to derive the optimal number of facilities in closed form. Analytical models are meant to provide insights rather than implementable solutions [34,65].

In *network* problems, we are given a graph or network with customers located on the nodes. Facilities may be located at nodes or anywhere along the arcs, and travel between customers and facilities occurs along the arcs. Specialized problems involving simple network topologies (such as trees) or a restricted number of facilities (1 or 2) may often be solved in polynomial time [66]. In general, network problems are formulated and solved using IP techniques.

A key property of network problems is the *Hakimi property* [67], which states that an optimal solution exists in which the facilities are all located at the nodes (rather than along the arcs of the network). This property reduces an infinite solution space to a finite (though combinatorially large) one. Unfortunately, the Hakimi property does not hold for all network problems; for example, it holds for the p -median problem on a network but not for the p -center problem (see the section titled “Classical Models”). When it does not hold, it is sometimes possible to guarantee that the optimal locations will be part of an augmented node set in which dummy nodes have been added along the arcs [68].

In *discrete* location models, we are given a discrete set of points at which the facilities

may be located. These problems are usually formulated and solved using IP techniques. Network models can be considered as a special case of discrete models if the Hakimi property applies (to the original node set or an augmented one); the distance between a given facility and customer is simply set to be the network distance between those two nodes.

In this article, the primary focus is on network and discrete models since they are the most extensively studied and the most commonly extended models.

Distance Measures

Most location models can accommodate a variety of distance measures, although many algorithms depend critically on the use of a specific measure, or on properties such as symmetry or the triangle inequality.

In many cases, travel times or costs are required, rather than distances. These can sometimes be obtained by multiplying the distance by a constant, or one might assume that the times or costs are specified explicitly in a matrix. In general, the terms *distance*, *travel time*, and *transportation cost* are used interchangeably here.

Several common distance measures are discussed below.

Euclidean. If points are located in the plane, the familiar Euclidean distance is a natural choice for the distance measure: the distance between points (x_1, y_1) and (x_2, y_2) is given by

$$\sqrt{(x_1 - x_2)^2 + (y_1 - y_2)^2}. \quad (1)$$

Rectilinear. This measure assumes that travel is possible only along lines that are parallel to one of the two axes. It is sometimes known as the *Manhattan metric* since it can represent travel in a city with a grid of perpendicular streets. The distance between (x_1, y_1) and (x_2, y_2) is given by

$$|x_1 - x_2| + |y_1 - y_2|. \quad (2)$$

Although this measure accurately reflects the distance in some situations, the reason for

using it is usually that it is mathematically more convenient than the Euclidean distance since it is piecewise linear rather than non-linear.

ℓ_p Norm. For a fixed constant $p \geq 1$, the ℓ_p distance between (x_1, y_1) and (x_2, y_2) is given by

$$(|x_1 - x_2|^p + |y_1 - y_2|^p)^{1/p}. \quad (3)$$

By setting $p = 1$ and $p = 2$, we get the rectilinear and Euclidean measures, respectively, as special cases. For general p , this norm is of more mathematical than practical interest.

Great Circle. All the measures discussed above assume that the points are located on the plane and do not represent geographical locations. For example, if locations are specified using latitude and longitude, the Euclidean distance formula does not apply. Instead, one can use great-circle distances, whose formula correctly interprets coordinates given as latitude and longitude and also accounts for the curvature of the Earth, assuming that travel occurs over a great circle (the shortest route over the surface of a sphere). Let (α_1, β_1) and (α_2, β_2) be the latitude and longitude of two points and let $\Delta\alpha$ and $\Delta\beta$ be the differences in the latitude and longitude (respectively). Then the great-circle distance between them is given by

$$2r \arcsin \left(\sqrt{\sin^2 \left(\frac{\Delta\alpha}{2} \right) + \cos \alpha_1 \cos \alpha_2 \sin^2 \left(\frac{\Delta\beta}{2} \right)} \right), \quad (4)$$

where r is the radius of the Earth, approximately 3958.76 miles or 6371.01 km (on average).

Highway. Highway distances reflect the true travel distance between two geographical points after solving a shortest-path problem on the road network that connects them. These distances can be obtained from web sites such as Mapquest or Google Maps, or from many geographic information systems (GIS). For most practical instances, this is the distance measure of choice.

Matrix. In some cases, the distance matrix, which lists the distance between each pair of points, is simply given explicitly. This is the most general measure: all of the measures listed above are special cases. Distance matrices are useful when the distance does not follow a predictable pattern—for example, if it represents freight rates or airline ticket prices. In the remainder of this article, it is assumed that this matrix is given and the details about how the distances were calculated are ignored.

Aggregate Distance Function

Another important element of a location model is the way in which it calculates an aggregate measure to summarize the distances between customers and their assigned facilities. The three most common aggregate distance functions are total distance, maximum distance, and coverage. Any of these can occur in either the objective function or the constraints, although the first two are most commonly found in the objective function.

In *total distance* models, the aggregate distance is calculated by simply summing the distances over all the customers; that is,

$$\sum_{\text{customers } i} \text{distance from } i \text{ to assigned facility.} \quad (5)$$

Often, the distances are weighted based on the demand of the customer or some other weighting factor:

$$\sum_{\text{customers } i} \text{weight}_i \cdot \text{distance from } i \text{ to assigned facility.} \quad (6)$$

Problems featuring this aggregate distance function are sometimes known as *minisum problems*. Examples include the *p*-median problem and the uncapacitated fixed-charge location problem (UFLP) (see the section titled “Classical Models”).

In *maximum distance* models, the aggregate distance is set equal to the maximum distance from a customer to its assigned facility:

$$\max_{\text{customers } i} \text{distance from } i \text{ to assigned facility.} \quad (7)$$

(This measure, too, has a weighted version.) This function is used to ensure some degree of service equity among the customers. Problems featuring this aggregate distance function are sometimes known as *minimax problems*. Examples include the *p*-center problem.

Finally, *coverage* models assume that a customer is “covered” if it is within a pre-specified radius of its assigned facility. Such models may require that all customers be covered by an open facility (as in the set covering location problem [SCLP]) or may cover as many (weighted or unweighted) customers as possible using a fixed number of facilities (as in the maximal covering location problem [MCLP]).

Limiting the Number of Facilities

Most aggregate distance functions encourage facilities to be close to customers, and this leads to a tendency to open many (or all) of the available facilities. To counteract this tendency, most facility location models include some mechanism for preventing too many facilities from being open. The two most common approaches are to use a fixed cost or to place an explicit restriction on the number of open facilities.

Fixed costs apply to each open facility and are independent of the volume of demand assigned to the facility. They represent overhead costs associated with the facility, such as real estate-related costs (construction, mortgage, or rent costs), heating and cooling, and some personnel costs. This is the approach taken by the UFLP (see the section titled “Classical Models”). Importantly, these costs must be expressed in the same time units as the demands. For example, if a facility costs \$24 million to build and is expected to be in use for 10 years, and if monthly demands are used as an input to the model, then the fixed cost should be given as \$200,000 ($=24,000,000/(10 \times 12)$) per month.

The other common way to limit the number of facilities is simply to include a *cardinality constraint* requiring at most *p* facilities to

be opened, for a constant integer $p \geq 1$. This is the approach taken by the p -median and p -center problems.

Some models use a hybrid approach consisting of a budget constraint restricting the total fixed cost of the opened facilities, rather than their cardinality.

CLASSICAL MODELS

Combining the various options in the dimensions listed above, a wide range of “fundamental” models can be obtained. From these, an even greater array of extensions and variants can be formulated. This section discusses six classical models that have served as the starting point for the majority of models that have been developed subsequently. Mathematical formulations and a brief discussion of the algorithmic approaches used are provided. The first model, the Weber problem, is a continuous model, while the other models are discrete or network models. The first three models are total distance models, the fourth is a maximum distance model, and the last two are coverage models.

The following notation is used throughout this section and the next. (Not all notation is used by every model.)

SETS

- I set of customers
- J set of potential facility sites

PARAMETERS

- h_i demand (items per unit time) at customer i , $\forall i \in I$
- c_{ij} cost to ship one item from facility j to customer i , $\forall i \in I, j \in J$
- f_j fixed cost per unit time to open facility j , $\forall j \in J$
- p maximum number of facilities to open

DECISION VARIABLES

- x_j 1 if facility j is opened, 0 otherwise, $\forall j \in J$
- y_{ij} 1 if facility j serves customer i , 0 otherwise, $\forall i \in I, j \in J$

The Weber Problem

Background and Formulation. In the Weber problem, we have to locate a single facility anywhere in a region Ω in order to minimize the total demand-weighted Euclidean distance from the facility to a set of fixed customer locations, also located in Ω . Since this is a continuous problem, we replace the notation c_{ij} with a function $c_i(x, y)$ that represents the distance from customer i to the point (x, y) , as given by Equation (1). The Weber problem is then formulated as follows:

$$(\text{WEBER}) \quad \text{minimize} \quad \left\{ \sum_{i \in I} h_i c_i(x, y) \right\} \quad (8a)$$

$$\text{subject to} \quad (x, y) \in \Omega \quad (8b)$$

This is a generalization of a 3-“customer” problem that is usually attributed to the seventeenth-century mathematician Pierre de Fermat.

Solution Methods. The Weber problem can be solved using a variety of iterative methods, most notably the so-called Weiszfeld procedure [69], or using standard nonlinear programming techniques. Special cases of the problem can be solved using geometric constructions such as Torricelli points or Simpson lines, and even by physical devices such as the Varignon frame [40].

Extensions include alternate distance metrics [70], multiple facilities [71], forbidden regions [72], travel barriers [73], and the location of dimensional (nonpoint) facilities such as lines [74]. For a more comprehensive discussion of the Weber problem and its variants, refer to Drezner *et al.* [40].

The p -Median Problem

Background and Formulation. The objective of the p -median problem (sometimes known as the k -median, m -median, etc.) is to locate p facilities so as to minimize the total demand-weighted transportation cost between customers and their assigned facilities. The most common formulation, due to Revelle and Swain [75], is as follows:

$$(p\text{MP}) \text{ minimize } \sum_{i \in I} \sum_{j \in J} h_i c_{ij} y_{ij} \quad (9a)$$

$$\text{subject to } \sum_{j \in J} y_{ij} = 1 \quad \forall i \in I \quad (9b)$$

$$y_{ij} \leq x_j \quad \forall i \in I, \forall j \in J \quad (9c)$$

$$\sum_{j \in J} x_j \leq p \quad (9d)$$

$$x_j \in \{0, 1\} \quad \forall j \in J \quad (9e)$$

$$y_{ij} \geq 0 \quad \forall i \in I, \forall j \in J. \quad (9f)$$

The objective function (9a) calculates the total demand-weighted transportation cost between customers and their assigned facilities. Constraints (9b) require each customer to be assigned to exactly one facility, and that facility must be open by constraints (9c). Constraint (9d) requires at most p facilities to be open. (At optimality, exactly p facilities will be open in most instances.) Constraints (9e) require the x variables to be binary, while (9f) require the y variables to be nonnegative. Although the y variables were defined to be binary, if we relax them to continuous variables, there always exists an optimal solution in which they are binary.

Solution Methods. The p -median problem is polynomially solvable for fixed p but is NP-hard for variable p [76]. Among the class of NP-hard problems, p -median is considered a relatively “easy” problem since it can be solved to optimality relatively quickly. One reason for this is that the LP relaxation is often extremely tight and in fact often produces integer solutions “for free” [75]. Nevertheless, a huge range of solution methods—both heuristic and exact—have been proposed for the p -median problem. Some of these are summarized next.

Heuristics. Perhaps the earliest and simplest heuristic for the p -median problem is the *greedy-add* heuristic [77], in which we start with all facilities closed and open the single facility that results in the smallest cost; then force that facility open and find a second facility that will reduce the objective function the most; then repeat until p facilities have been opened.

The *neighborhood search* heuristic [78] begins with any feasible solution and iteratively repeats two main steps. In the first, we find the 1-median (a trivial problem) in the “neighborhood” of each facility, defined as the set of customers the facility serves. If any facility is not equal to the 1-median in its neighborhood, we replace it with the 1-median, guaranteeing a decrease in the objective function. If any facilities have been replaced in this manner, we proceed to the second step, in which we reassign each customer to its nearest open facility, creating new neighborhoods. We repeat this process until a given iteration makes no modifications to the solution.

Another well-known improvement heuristic is the *interchange* (or *exchange*) heuristic [79], which searches for pairs of facilities—one open, one closed—such that the objective function would improve if we “swap” the two facilities—that is, open the closed facility and close the open one. We repeat this until no improving swaps are found. Variants of this heuristic have been applied to a wide range of facility location problems, not just to the p -median. If applied directly, this heuristic is more computationally burdensome than the greedy-add heuristic since it relies on evaluating $O(|J|^2)$ swaps at each iteration, while greedy-add evaluates $O(|J|)$ moves. However, the *fast interchange* heuristic of Whitaker [80] (later refined by Hansen and Mladenović [81]) implements the same idea in a much more efficient manner so that the moves have similar complexity to those in greedy-add.

Since the mid-1990s, there has been an explosion in the development of *metaheuristics*—heuristics that are designed to be general enough to apply to many combinatorial optimization problems with little customization required. A great many of these have been applied to the p -median problem; these include tabu search [82], genetic algorithms [83], variable neighborhood search [81], simulated annealing [84], heuristic concentration [85], ant colony optimization [86], and neural networks [87]. For a review of metaheuristics applied to the p -median problem, see Mladenović *et al.* [39].

Exact Algorithms. The p -median problem can be solved using straightforward branch and bound methods because of its tight LP relaxation [75,88]. A host of other exact algorithmic approaches have been introduced for the problem, many of which were preferable to branch and bound when those methods were first developed since LP codes at that time were significantly less efficient than they are now. Moreover, some of these algorithms are more easily extended to problem variants (e.g., nonlinear objectives) compared to LP-based methods. Classical optimization methods that have been applied to the p -median problem include branch and bound [75], branch and cut [89], dual-based approaches [90], LP decomposition [91], and graph-theoretic bounds [92]. For further information on the range of techniques that have been proposed, see the annotated bibliography by Reese [38].

The most popular exact algorithm for solving the p -median problem (and many of its variants) seems to be *Lagrangian relaxation*, in which a set of constraints is removed and a penalty for violation is inserted into the objective function. The method was first applied to a p -median-like problem by Cornuejols *et al.* [13], although their model also includes fixed costs in the objective function and is therefore a hybrid between the p -median problem and the UFLP (see the section titled “The Uncapacitated Fixed-Charge Location Problem”). Fisher [93] discusses the method for a problem identical to that of Problem (9). The idea is to relax constraints (9b) to obtain the following problem for fixed Lagrange multipliers λ :

$$\begin{aligned} (pMP-LR_\lambda) \quad & \text{minimize} \\ & \sum_{i \in I} \sum_{j \in J} h_i c_{ij} y_{ij} + \sum_{i \in I} \lambda_i \left(1 - \sum_{j \in J} y_{ij} \right) \\ & = \sum_{i \in I} \sum_{j \in J} (h_i c_{ij} - \lambda_i) y_{ij} + \sum_{i \in I} \lambda_i \end{aligned} \quad (10a)$$

subject to

$$y_{ij} \leq x_j \quad \forall i \in I, \forall j \in J \quad (10b)$$

$$\sum_{j \in J} x_j \leq p \quad (10c)$$

$$x_j \in \{0, 1\} \quad \forall j \in J \quad (10d)$$

$$y_{ij} \geq 0 \quad \forall i \in I, \forall j \in J. \quad (10e)$$

This problem is trivial to solve. If we open facility j , we would set $y_{ij} = 1$ if $h_i c_{ij} - \lambda_i < 0$ and to 0 otherwise. Therefore, the “benefit” from opening facility j is given by

$$\beta_j = \sum_{i \in I} \min\{0, h_i c_{ij} - \lambda_i\}. \quad (11)$$

To solve $(pMP-LR_\lambda)$, we open the p facilities with the smallest values of β_j and assign customers to facilities based on the sign of $h_i c_{ij} - \lambda_i$. Of course, this solution will almost certainly not be feasible for (pMP) since some customers will be assigned to multiple facilities and some not at all. However, for any λ , the optimal objective value of $(pMP-LR_\lambda)$ provides a lower bound on that of (pMP) , which is useful for evaluating feasible solutions. In fact, the solution to $(pMP-LR_\lambda)$ itself can be used to generate a feasible solution: we simply keep the same p facilities open and assign each customer to its nearest open facility.

These steps—generating lower and upper bounds—are performed iteratively, and at the end of each iteration, the Lagrange multipliers λ are updated using subgradient optimization or some other method. The algorithm terminates when the lower and upper bounds are sufficiently close or when another stopping criteria (such as a limit on the number of iterations) is triggered. In the latter case, branch and bound can be used to narrow the gap between the bounds; at each node of the branch and bound tree, lower bounds are obtained using Lagrangian relaxation, rather than using LP relaxation as in the standard branch and bound method. This method is capable of solving problems with hundreds or thousands of facilities in seconds on a desktop computer [94]. For additional details about this method and other possible relaxations, see Daskin [22] and Fischer [93].

The Uncapacitated Fixed-Charge Location Problem

Background and Formulation. The UFLP is similar to the p -median problem except that it has no restriction on the number of open

facilities and it includes a fixed cost for opening each facility in the objective function. The UFLP (also known as the *simple plant location problem* [SPLP] as well as a variety of other similar names) can be formulated as follows:

(UFLP) minimize

$$\sum_{j \in J} f_j x_j + \sum_{i \in I} \sum_{j \in J} h_i c_{ij} y_{ij} \quad (12a)$$

$$\text{subject to } \sum_{j \in J} y_{ij} = 1 \quad \forall i \in I \quad (12b)$$

$$y_{ij} \leq x_j \quad \forall i \in I, \forall j \in J \quad (12c)$$

$$x_j \in \{0, 1\} \quad \forall j \in J \quad (12d)$$

$$y_{ij} \geq 0 \quad \forall i \in I, \forall j \in J. \quad (12e)$$

The constraints are identical to those for (pMP) except for the exclusion of (9d). Hence we do not discuss them further.

Solution Methods. The UFLP is NP-hard [95] but, similar to the p -median problem, it is considered relatively “easy” nevertheless. Variants of many of the heuristics described in the section titled “Solution Methods” on p.6 have also been applied to the UFLP, for example, the greedy heuristic [77]. So have the exact solution methods, such as branch and bound [88]. The Lagrangian relaxation approach described in the section titled “Solution Methods” on p.6 is also readily applicable; the only change is that, rather than opening the p facilities with the smallest β_j , we instead open *any* facility for which $\beta_j + f_j < 0$ (that is, for which the benefit outweighs the fixed cost).

Another important exact algorithm for the UFLP is Erlenkotter’s DUALOC algorithm [96], which operates on the dual of the LP relaxation. The first step is a *dual ascent procedure* that starts with a given dual solution, attempts to improve it, and then derives a primal feasible solution from it. If these solutions are optimal, the procedure terminates; otherwise, a *dual adjustment procedure* attempts to reduce complementary slackness violations in order to improve the primal/dual pair. Branch and bound is used in the event that the resulting primal solution is not an integer.

The p -Center Problem

Background and Formulation. The p -center problem locates p facilities in order to minimize the maximum distance between a customer and its assigned facility. The p -center problem was first proposed by Hakimi [67]. On a network, the Hakimi property does not apply—that is, the optimal locations may not lie at the nodes of the network. (Imagine locating a single facility on a network consisting of two nodes and an arc connecting them; the optimal solution is to locate halfway along the arc itself.) The literature, therefore, often distinguishes between the “vertex” p -center problem, in which facilities must be located at nodes, and the “absolute” p -center problem, in which facilities may be located on arcs. In either case, the demand nodes may be weighted or unweighted. Using the notation already introduced, the weighted vertex p -center problem can be formulated as follows:

$$(pCP) \text{ minimize } w \quad (13a)$$

$$\text{subject to } \sum_{j \in J} y_{ij} = 1 \quad \forall i \in I \quad (13b)$$

$$y_{ij} \leq x_j \quad \forall i \in I, \forall j \in J \quad (13c)$$

$$\sum_{j \in J} x_j \leq p \quad (13d)$$

$$\sum_{j \in J} h_i c_{ij} y_{ij} \leq w \quad \forall i \in I \quad (13e)$$

$$x_j \in \{0, 1\} \quad \forall j \in J \quad (13f)$$

$$y_{ij} \in \{0, 1\} \quad \forall i \in I, \forall j \in J. \quad (13g)$$

The objective function (13a) consists simply of a new decision variable, w , which represents the maximum weighted distance of a customer to its assigned facility. This interpretation of w is enforced through constraints (13e), which require w to be no smaller than the weighted assigned distance for each customer. Constraints (13b)–(13d) are identical to constraints (9b)–(9d) in the p -median problem. Note that the assignment variables (y) must be enforced as binary in constraint (13g); it is not sufficient to relax these constraints, as it is in the p -median problem.

Solution Methods. Similar to the p -median problem, the p -center problem can be solved in polynomial time for fixed p but is NP-hard for variable p [97]. Largely due to its minimax structure, the p -center problem does not lend itself nearly as well as the p -median problem to LP-based approaches or to Lagrangian relaxation. One common approach for solving the unweighted version is to iteratively solve the SCLP (see next section) by applying a line search on the coverage radius. The optimal objective value of the p -center problem is the smallest r such that the optimal objective value of the set covering problem with coverage radius r equals p [98]. The method can be extended fairly easily to the weighted case [19]. An important algorithm for the continuous version of the problem, due to Drezner and Wesolowsky [99], uses numerical integration of ordinary differential equations.

The Set Covering Location Problem

Background and Formulation. The SCLP, and the MCLP discussed in the next section, both make use of the notion of *coverage*: A customer is considered “covered” if there is an open facility within a prespecified radius r (measured by distance, travel time, or transportation cost). The objective of the SCLP is to minimize the total number of facilities located while covering every customer. For more details on the SCLP, see Mirchandani and Francis [21] and Snyder [41].

The SCLP was first introduced in the context of facility location by Hakimi [100]. (The graph-theoretic vertex cover problem, which had been studied well before Hakimi’s article, can be considered a special case of the SCLP in which $I = J$; $d_{ij} = 1$ for all i, j ; and $r = 1$. In fact, it is this special case that Hakimi’s article considers, although he is usually credited with introducing the general SCLP.)

Let $N_i = \{j \in J : c_{ij} \leq r\}$ be the set of facilities that cover customer i . The following mathematical programming formulation is due to Toregas *et al.* [101]:

$$(\text{SCLP}) \text{ minimize } \sum_{j \in J} x_j \quad (14a)$$

$$\text{subject to } \sum_{j \in N_i} x_j \geq 1 \quad \forall i \in I \quad (14b)$$

$$x_j \in \{0, 1\} \quad \forall j \in J. \quad (14c)$$

The objective function (14a) simply calculates the number of open facilities. (Alternately, the x_j can be weighted by f_j to minimize the total fixed cost of the opened facilities.) Constraints (14b) ensure that, for each customer i , at least one facility that covers i is open.

The Hakimi property does not apply to the SCLP; a counterexample consists of a single edge of length 1 connecting two nodes, and a coverage radius of $r = 0.5$.

Solution Methods. The SCLP is NP-hard [95]. Hakimi [100] proposed a solution method using Boolean functions that requires enumerating all coverings and is therefore impractical for realistic instances. Instead, the SCLP is generally solved using IP techniques, the first of which was proposed by Toregas *et al.* [101], who formulated the problem as in problem (14) and used LP branch and bound to solve it. This formulation typically has a small (often zero) integrality gap [102], and Toregas *et al.* [101] suggest a cut that strengthens the LP relaxation further. The size of the IP itself can often be reduced by eliminating dominated columns (i.e., facilities whose covered customers are a subset of another facility’s) and dominated rows (i.e., customers whose covering facilities are a superset of another customer’s) [103]. A large body of literature also exists for solving general (i.e., not facility-location-specific) set covering problems [104], and these algorithms also apply to the SCLP.

The Maximal Covering Location Problem

Background and Formulation. The MCLP [105] can be thought of as the inverse of the SCLP: the SCLP minimizes the number of facilities required to cover all customers, while the MCLP maximizes the total demand of covered customers subject to a limit on the number of facilities opened. One important advantage of the MCLP over the SCLP is that it accounts for differences in customer

demands (and therefore importance) rather than treating all customers as identical, as the SCLP does.

Let z_i be a decision variable that is equal to 1 if customer i is covered and 0 otherwise, and define N_i as the set of facilities that cover customer i , as above. Then the MCLP can be formulated as follows:

$$\text{(MCLP) maximize } \sum_{i \in I} h_i z_i \quad (15a)$$

$$\text{subject to } z_i \leq \sum_{j \in N_i} x_j \quad \forall i \in I \quad (15b)$$

$$\sum_{j \in J} x_j \leq p \quad (15c)$$

$$x_j \in \{0, 1\} \quad \forall j \in J \quad (15d)$$

$$z_i \in \{0, 1\} \quad \forall i \in I. \quad (15e)$$

The objective function (15a) calculates the total covered demands. Constraints (15b) prevent a customer from being considered covered unless some covering facility has been opened. Constraints (15c) require at most p facilities to be opened.

Solution Methods. The MCLP is NP-hard [106] but, like several of the problems discussed so far, it generally has a fairly tight LP bound. Church and ReVelle [105] report that the LP relaxations of the majority of their test instances have integer solutions, and they use branch and bound to solve the remainder of the problems. They also propose a method for solving a problem for consecutive values of p ; it attempts to create an integer solution for the p -facility problem using a fractional solution for that problem and an integer solution for the $(p - 1)$ -facility problem. Lagrangian relaxation, relaxing constraints (15b), is also effective [107,108].

Heuristic methods have been proposed, including greedy-add [109]; greedy adding with substitution (GAS) [105], which combines greedy-add with an exchange heuristic; and metaheuristics [110,111].

EXTENSIONS

A broad literature has arisen that builds on the classical models discussed in the section

titled “Classical Models” to develop richer models that address more realistic and more nuanced issues. In this section several topics that have emerged over the past few decades are discussed briefly.

Hazardous Facility Location Problems

The models discussed in the section titled “Classical Models” all aim to locate facilities close to customers. However, for some facilities—for example, prisons and nuclear waste sites—the opposite is desired. So-called *hazardous facility location problems* account for this by maximizing the distance between facilities and customers or among the facilities themselves.

Obnoxious facility location problems attempt to maximize the distance between customers and facilities. The *maxisum problem* is the opposite of the p -median problem in that it locates p facilities in order to *maximize* the demand-weighted distance between customers and their nearest facilities. The formulation is a bit more complicated than simply changing the sense of constraint (9a) from minimize to maximize, since doing so would cause the model to assign customers to their farthest facilities. Instead so-called “closest assignment” constraints ensure that customers are assigned to their nearest opened facilities. Goldman and Dearing [112] and Church and Garfinkel [113] introduce the 1-facility version; Drezner and Wesolowsky [114] study the p -facility version. Similarly, the *maximin problem* is a maximization version of the p -center problem.

The *p -dispersion problem* [115,116] seeks to maximize the minimum distance between facilities—customers are entirely omitted from the problem. For example, the military may wish to disperse arms depots geographically to reduce the risk of a simultaneous attack, or a retailer may wish to keep branch outlets at some distance from one another to avoid cannibalization.

See Erkut and Neuman [42] and Cappanera [43] for reviews of these and other hazardous location problems.

Dynamic Location Problems

Dynamic location problems assume that facilities may be opened, closed, or moved

over time, either due to limited budgets that prevent all facilities from being opened at once, or in response to changes in the problem parameters (demands, costs, etc.). (A closely related body of literature assumes that the parameters change stochastically over time, but these models usually assume that facility locations are static; see the section titled “Stochastic and Robust Models”). Examples include [117–123]; for a review, see Owen and Daskin [52].

Hierarchical Location Problems

The classical models make facility location decisions for a single echelon (or layer)—for example, plants, warehouses, or retailers. In practice, it is often important to make decisions about multiple echelons simultaneously, including both location and flow decisions. Such problems are known as *hierarchical location problems* [124–126]; see the reviews by Narula [44] and Sahin and Süral [45]. Many hierarchical problems also include multiple commodities, building on the seminal (single-echelon) multicommodity location model by Geoffrion and Graves [127]. This topic is also closely related to network design problems, in which the objective is to locate arcs, rather than nodes, of the network [128,129].

Competitive Location Problems

In *competitive location problems*, two or more players locate facilities in order to maximize their own profit or market share. The typical example concerns two competing retail or restaurant chains (Home Depot and Lowe’s, McDonald’s and Burger King) that are near substitutes so that consumers choose one over the other, largely based on proximity. The earliest such model is by the economist Hotelling [130], who considered a continuous version of the problem. Most subsequent works consider discrete or network versions [131,132]; for reviews, see Plastria [46] and Eiselt *et al.* [47].

Hub Location Problems

Whereas classical facility location problems involve flows between facilities and customers, *hub location problems* also involve

flows among the facilities. The motivation comes from airlines, third party logistics companies, and other firms that operate hub-and-spoke systems. In such systems, interfacility flows are as important as, or more important than, facility–customer flows, in part because they often use a more cost-effective mode of transportation (e.g., larger-capacity trucks or airplanes). Demands in hub location problems are usually expressed as customer-to-customer flows; that is, they are origin-and-destination-specific, whereas classical problems use destination-specific demands. The standard formulation for the basic problem of locating p hubs to minimize the total transportation cost [3] has the same constraints as the p -median problem, but its objective is quadratic in the assignment variables to capture the intrafacility flows, making the problem significantly more difficult to solve. For surveys of the literature on hub location, see O’Kelly and Miller [48] and Campbell *et al.* [49].

Facility Congestion

Facility congestion refers to the fact that a customer wishing to use a facility may find it already in use. A classic example is the location of ambulances or fire trucks. Facility location problems with congestion account for this possibility when deciding on where to locate facilities (and, sometimes, the number of servers to locate at each facility). These are essentially queueing problems in which the facility or server is the service mechanism; customers finding no servers available must wait in queue. The hypercube model of Larson [133,134] models this queueing process explicitly, but the resulting expressions are generally too complex to embed into optimization models. Instead, most of the research has focused on approximating the probability that a customer finds an available server, and building enough redundancy to ensure that this probability is sufficiently high. Daskin’s [135,136] maximum expected covering location model (MEXCLM) is an extension of the MCLP that maximizes the total expected coverage assuming that all facilities have the same availability probability; it has served as the basis for a host of other models that

relax this assumption in various ways; for reviews, see Daskin *et al.* [50] and Berman and Krass [51].

Stochastic and Robust Models

Stochastic and robust location models account explicitly for the fact that demands, costs, and other parameters may be stochastic or unknown at the time when facility location decisions are made. Uncertain parameters are generally represented as scenarios (for which probabilities may or may not be known) or as intervals in which the parameters are assumed to lie. The problems are modeled and solved using stochastic optimization (which optimizes the expected value of the objective function) or robust optimization (which optimizes some other measure of uncertainty, typically reflecting some measure of risk aversion). Stochastic problems tend to be easier to solve than robust problems, which are usually solved exactly for special cases or heuristically for general problems. The earliest articles on this topic extend classical models such as the p -median or UFLP, minimizing the expected cost [137,138], a mean–variance objective [139], or the worst-case cost or regret [140]. For reviews of stochastic and robust problems, see Owen and Daskin [52], Louveaux [53], and Snyder [54].

A related stream of literature considers uncertainty from the supply side in the form of facility or supplier disruptions, during which customers must be assigned to backup facilities. One set of models assumes that facilities are stochastically disrupted [141–143], while another assumes that facilities are interdicted by a malicious entity. The latter models either determine the worst-case damage that can be caused for a given set of facilities [144] or determine which facilities to “fortify” to protect against this worst-case damage [145]. For reviews of facility location problems with disruptions, see Snyder and Daskin [55] and Snyder *et al.* [56,57].

Integrated Location Models

The term *integrated location models* generally refers to models that integrate facility location (a strategic decision) with tactical or

operational decisions, most commonly vehicle routing or inventory. Location–routing models recognize that deliveries are often made using less-than-truckload (LTL) shipments, in which the transportation cost from a facility to a customer depends on which other customers are also served by that facility. In contrast, classical location models assume full truckload (TL) deliveries, in which the transportation cost is independent of other deliveries. Location–routing problems are generally quite difficult to solve, since they combine two NP-hard problems, facility location and vehicle routing. They typically either model the outbound flows from facilities to customers [146,147], or model both the outbound flows and the inbound (TL) flows from suppliers to facilities [148]. For reviews of location–routing models, see Laporte [58], Min *et al.* [59], and Daskin *et al.* [60].

Location–inventory models incorporate the cost of managing inventory into the objective function of a facility location problem. Nozick and Turnquist [149] formulate a model in which the cost of a base-stock policy at each facility is approximated by a linear function that is embedded into a model similar to the UFLP. Shen *et al.* [150] and Daskin *et al.* [151] formulate a similar model but include the nonlinear inventory costs of both cycle stock and safety stock, accounting for economies of scale in ordering as well as the risk-pooling effect [152]. As a result, the solutions of their model tend to open fewer facilities than those of the UFLP. The model can be solved nearly as efficiently as the UFLP using either column generation [150] or Lagrangian relaxation [151]. For reviews of location–inventory models, see Shen [61] or the article titled **Introduction to Facility Location** in this encyclopedia.

Public Sector Models

Although most facility location models can be applied either in the private or in the public sector, models that focus primarily on cost or profit objectives (such as the p -median and UFLP) tend to be most applicable in the private sector, while those that use coverage or equity objectives (such as the p -center, SCLP, and MCLP) are more readily applied to the public sector. Marianov and Serra

[62] review these latter models, in addition to models with congestion (see the section titled “Facility Congestion”), and public sector modifications of the p -median problem. These models and their extensions have been applied to the location of subsidized housing [153], humanitarian relief agencies [154], and wildlife reserve sites [11].

CONCLUSION

This article has provided a broad overview of the field of facility location. For the sake of brevity, many related topics are omitted, which can be found described in the articles listed below, or in the references cited therein. It is hoped that this article will serve as a useful reference for those actively working in the field of facility location, as well as a helpful starting point for those just beginning to explore it.

Most of the extensions discussed in the section titled “Extensions” are active areas of research. Future research areas will likely include modeling and solution techniques for problems with nonlinearities (such as economies of scale), large-scale problems with a great many nodes or scenarios, problems that exhibit multiple temporal or geographical scales, models to hedge against supply chain risk, and problems with humanitarian and environmental benefits.

and Systems Engineering, University of
Southern California, Los Angeles,
California

INTRODUCTION

Linear programming (LP) has been used as an effective tool to solve a number of applications in manufacturing, transportation, military, health care, and finance. In order to accurately model practical systems, however, there may be many variables and constraints necessary to capture all of the attributes in the problem. In many applications, the size of the formulation in terms of the number of variables and constraints can be quite large. For example, Gondzio and Grothey [1] solve problems with variable sizes up to 10^9 and Leachman [2] formulates an LP model of over 10^5 constraints to solve a production planning problem for semiconductors at Harris Corporation. With such large-size problems, specialized procedures such as column generation and cutting-plane methods may need to be employed to solve them. In some cases, the problem may have a special structure, where decomposition methods can also be used. The purpose of this article is to provide an overview of these specialized procedures, and we conclude with an example of a large-scale formulation for solving a route balancing problem. For general discussion on the progress made with LP, problem size, and algorithmic developments one may refer to Bixby [3]. In this article, we describe some of the fundamental ideas used in large-scale LP with an emphasis on the simplex method. However, the reader may also refer to the literature on interior point methods [4,5,11].

LINEAR PROGRAMMING PROBLEM

Consider the following standard LP problem:

$$\min \mathbf{c}^\top x \quad (1)$$

$$\text{s.t. } \mathbf{A}x = \mathbf{b} \quad (2)$$

$$x \geq 0, \quad (3)$$

where $x \in \mathbb{R}^n$, $\mathbf{A}$ is an $m \times n$ matrix, and $\mathbf{c}$ and $\mathbf{b}$ are vectors of length n and m , respectively. Now suppose the problem is so large, for example, the $\mathbf{A}$ matrix cannot be stored in memory, that the LP cannot be solved. Using the simplex method, large-scale problems can be solved by adding a few extra steps to the algorithm. Depending on the structure of the $\mathbf{A}$ matrix it may be possible to decompose the problem such that solving smaller subproblems provides sufficient optimality conditions. Recall from the simplex method, an LP is partitioned into Basic (B) and Nonbasic (N) elements. Such a partitioning on Equations (1)–(3) gives

$$\min \mathbf{c}_B^\top x_B + \mathbf{c}_N^\top x_N \quad (4)$$

$$\text{s.t. } \mathbf{B}x_B + \mathbf{N}x_N = \mathbf{b} \quad (5)$$

$$x_B, x_N \geq 0, \quad (6)$$

where $\mathbf{B}$ is an $m \times m$ matrix composed of the set of linearly independent columns $\mathbf{A}_i \forall i \in B$ ($\mathbf{A}_i$ refers to column i in the $\mathbf{A}$ matrix), $\mathbf{N}$ is a matrix composed of the remaining set of columns $\mathbf{A}_j \forall j \in N$, $\mathbf{c}_B$ refers to the vector in the objective function containing the elements in B , and $\mathbf{c}_N$ refers to the elements in N . Also, x_B and x_N refer to the basic and nonbasic decision variables, respectively. Finally, $\mathbf{B}^{-1}$ exists since the columns of $\mathbf{B}$ are linearly independent. Then, solving for x_B in Equation (5) and making the substitution in Equation (1) provides

$$\min \mathbf{c}_B^\top \mathbf{B}^{-1} \mathbf{b} + (\mathbf{c}_N^\top - \mathbf{c}_B^\top \mathbf{B}^{-1} \mathbf{N}) x_N. \quad (7)$$

A basis matrix $\mathbf{B}$ is then said to be optimal

if $\mathbf{c}_N^\top - \mathbf{c}_B^\top \mathbf{B}^{-1} \mathbf{N} \geq 0$ and $\mathbf{B}^{-1} \mathbf{b} \geq 0$. The first argument is provided in Equation (7); if the value in parenthesis is nonnegative then introducing a nonbasic element to B offers no further reduction to the current objective value, which proves the optimality of the solution. Although we will not go through all the details of the algorithm, the simplex method tries to find a set of basic variables that satisfy the optimality criteria. To do so, given an initial basis, reduced costs r_j are defined $\forall j \in N$, where

$$r_j = \mathbf{c}_j - \mathbf{c}_B^\top \mathbf{B}^{-1} \mathbf{A}_j. \quad (8)$$

The primal simplex method then allows variables to enter and leave the basis while upholding $\mathbf{B}^{-1} \mathbf{b} \geq 0$, and, thus, for a given iteration if $r_j \geq 0 \forall j \in N$ the current basis is optimal. This observation is a critical step in many large-scale applications. Given the current basis, one method is to search for a new variable $x_j \forall j \in N$ to enter the basis if its reduced cost is *not* nonnegative; otherwise, the current solution is optimal. In the following sections, we investigate such applications.

COLUMN GENERATION

Many practical problems involve large-scale models where there are many more variables than constraints; hence, $n \gg m$. As mentioned in the last section, these instances may be quite difficult to solve. For such problems, column generation is an effective solution method. Column generation can also be used for problems where columns may be dynamically generated to form possible solutions. The general idea behind the algorithm is to find the subset of m basic variables that needs to be considered in the solution to the problem since nonbasic variables are equal to zero. To do so, the method forms a subset of the columns in Equations (1)–(3) called the *master problem*, which contains the columns associated with a basic feasible solution to the original problem and possibly a few additional columns. The method then searches for variables that have the potential to reduce the current objective value, which

is computed in a *subproblem* that identifies an entering variable. This implies finding a variable $x_j \forall j \in N$ with a reduced cost $r_j < 0$. The column generation algorithm proceeds as follows: first a master problem is generated involving a subset of the original variables, which contains an initial basis. Then a subproblem is solved to find an entering variable and the corresponding column is added to the master problem. The master problem is then re-solved and this process continues until the subproblem cannot identify an entering variable (i.e., $r_j \geq 0 \forall j \in N$), in which case the current solution is optimal. The master problem is defined as

$$\min \sum_{\omega \in \Psi} \mathbf{c}_\omega x_\omega \quad (9)$$

$$\text{s.t.} \quad \sum_{\omega \in \Psi} \mathbf{A}_\omega x_\omega = \mathbf{b} \quad (10)$$

$$x \geq 0, \quad (11)$$

where, for example, $\Psi = \{i \in B, j\}$, which contains all of the current basic columns and a nonbasic column $\mathbf{A}_j$. Then a subproblem is introduced that is used to seek a new column with $r_j < 0$ to add to the master problem. Re-solving the master problem will generate a new solution and the process is continued until $r_j \geq 0$ for all variables in the subproblem. We provide an example of a possible subproblem using Equation (16). One may also note that there are different techniques used to store the number of elements in set Ψ of the master problem. In the example described above, the size of Ψ is kept to a minimum of $m + 1$ variables. Other methods never remove any variables that have entered the basis, and some allow Ψ to grow to a certain size before removing variables. Using any of these sizes of Ψ and solving Equations (9)–(11) by adding columns in an iterative manner as described above is guaranteed to terminate in the absence of degeneracy since it is simply a special implementation of the revised simplex method. If degeneracy is present in the problem, one can use a method to prevent cycling such as the lexicographic rule.

Column generation is also an effective tool at solving problems where instead of

defining a large set of decisions, the problem may be more efficiently approached if it is structured to generate candidate solutions (columns) until a better solution cannot be found. Such problems exist in inventory, transportation, and scheduling. In the section titled “Route Balancing Example,” we provide an example where road crews are assigned to clean various areas of Los Angeles based on distance. As is presented, the problem can be expressed as

$$\min \mathbf{e}^\top x \quad (12)$$

$$\text{s.t. } Ax = \mathbf{b} \quad (13)$$

$$x \geq 0, \quad (14)$$

where $\mathbf{e}$ is a vector of all ones. As mentioned above, matrix A may not involve the set of all possible combinations to solve the initial problem and candidate solutions will be generated to do so. In this case, candidate solutions are equivalent to adding columns A_j to the problem. In the route balancing example, finding a candidate solution (column A_j) simply requires finding an area that a crew may be allocated to. Thus, providing an initial basis to Equations (12)–(14) and possibly a few additional columns forms the master problem. Suppose that we have an initial basis, then the subproblem will generate an additional candidate solution j with a negative reduced cost, that is,

$$r_j = 1 - \mathbf{e}^\top B^{-1}A_j < 0. \quad (15)$$

Now say that the subproblem generated columns associated with the most negative reduced cost. This is equivalent to taking the column associated with

$$\min\{r_j\} = \min \left\{ 1 - \mathbf{e}^\top B^{-1}A_j \right\}. \quad (16)$$

If the solution to the reduced cost found in Equation (16) is nonnegative, then the current solution is optimal. Notice that solving Equation (16) is equivalent to the following inequality:

$$\max \left\{ \mathbf{e}^\top B^{-1}A_j \right\} \leq 1. \quad (17)$$

Thus, the master problem is optimal if the solution to the subproblem satisfies Equation (17). In addition to Equation (17), the subproblem also involves constraints that satisfy the original problem such that only feasible solutions are considered. In some cases, the subproblem may simply require solving the knapsack problem. For more information and examples of such issues the reader may refer to Refs 6–8.

CUTTING-PLANE METHODS

In the section titled “Column Generation,” we discussed large-scale problems where $n \gg m$. We now examine the case in which the problem involves a large number of constraints. This is equivalent to investigating the dual of the model presented in the section titled “Column Generation.” In this case, we define problems where *cutting-plane* methods provide a valid solution approach. Considering the dual of Equations (1)–(3)

$$\max \mathbf{b}^\top y \quad (18)$$

$$\text{s.t. } A^\top y \leq \mathbf{c}, \quad (19)$$

where the resulting problem above has many rows or constraints. In order to solve the problem in Equations (18) and (19), the cutting-plane method defines a less-constrained problem

$$\max \mathbf{b}^\top y \quad (20)$$

$$\text{s.t. } A_\omega^\top y \leq \mathbf{c}_\omega, \quad \forall \omega \in \Omega, \quad (21)$$

where Ω is a subset of the constraints in the initial problem (i.e., $A_\omega^\top$ corresponds to a row in Equation (19)). The less-constrained problem in Equations (20)–(21) is referred to as the *relaxed* problem. The cutting-plane algorithm begins by first solving the relaxed problem, then uses a subproblem to check the feasibility of the solution with that of the initial problem in Equations (18)–(19). If a constraint is violated in the initial problem, then the violated constraint is added to subset Ω in the relaxed problem and it is re-solved. This continues until the optimal solution of the relaxed problem produces a

feasible solution with respect to the initial problem, at which point we have found an optimal solution. Thus, the algorithm continuously solves the relaxed problem with at least one additional constraint being added to Ω after each iteration, until an optimal solution is found that does not violate the initial problem. Given that y_Ω^* is an optimal solution to Equations (20)–(21), using the cutting-plane method there are two issues to consider with respect to the optimality of Equations (18)–(19), namely:

- (i) If y_Ω^* is a feasible solution to Equations (18)–(19), then $y_D^* = y_\Omega^*$; where y_D^* refers to an optimal solution of Equations (18)–(19).
- (ii) If y_Ω^* is infeasible with respect to Equations (18)–(19), then we find the violated constraint(s) and add it to the relaxed problem (Eqs 20 and 21). Thus, given that row $A_j^\top$ provides the violation, set Ω is updated to include row j and the problem is re-solved.

Figure 1 is a graphical illustration of cases (i) and (ii) above. Given that the feasible region of the initial problem is A_1 , if constraint L_4 is not included in the relaxed problem (Eqs 20 and 21), then the feasible region expands to contain regions $A_1 \cup A_2$. In this case, solving the relaxed problem produces an optimal solution to Equations (18)–(19) and, thus, $y_\Omega^* = y_D^*$. However, if constraint L_2 is not included in the relaxed problem (Eqs 20 and 21), then the feasible region contains $A_1 \cup A_3$. Depending on the slope of the objective function and the rest of the region, the optimal solution may be at vertex y_Ω^* , as depicted in the figure. In this case, $y_\Omega^* \neq y_D^*$, and violated inequality L_2 would be generated as a cutting plane.

The last issue to consider with respect to the cutting-plane algorithm is how to check that the solution is feasible with respect to the initial problem. Also, if the solution is not feasible, an efficient method to identify the violated constraint(s) is necessary. Given that y^k is the current solution to the relaxed problem, one method to identify a violated

Figure 1. Illustrative example of issues related to Cutting-plane methods.

constraint(s) involves solving

$$\min_{\ell \notin \Omega} \mathbf{c}_\ell - \mathbf{A}_\ell^\top y^k \quad (22)$$

from the variables in the initial problem (Eqs 18 and 19). This forms the subproblem in the cutting-plane method, and if Equation (22) is nonnegative for all elements ℓ then we have a feasible and, therefore, an optimal solution. Otherwise, we add a constraint that satisfies the inequality $\mathbf{A}_\ell^\top y^k > \mathbf{c}_\ell$ to the relaxed problem (Eqs 20 and 21). Depending on the problem, solving Equation (22) may be challenging. There are techniques that may be employed for such instances; the reader may refer to Refs 6 and 7 for more information on this topic. One may also note that the cutting-plane method we describe in this section is different than the method used in integer programming, where constraints (cuts) are added to the problem to form the convex hull of the integer feasible set; please refer to Ref. 9 for more on this topic.

SPECIAL DECOMPOSITIONS

In addition to the methods mentioned in the sections titled “Column generation” and “Cutting-Plane Methods,” many large-scale problems may have special structures that can be further exploited. For example, some problems may contain a *sparse* $\mathbf{A}$ matrix and/or have a unique *block-matrix* structure.

In some cases it is possible to decompose the large-scale system into smaller, more tractable problems. In a simple example, consider the following problem with a block diagonal matrix structure:

$$\min \bar{\mathbf{c}}_1^\top \bar{\mathbf{x}}_1 + \bar{\mathbf{c}}_2^\top \bar{\mathbf{x}}_2 + \cdots + \bar{\mathbf{c}}_n^\top \bar{\mathbf{x}}_n \quad (23)$$

$$\text{s.t. } \hat{\mathbf{D}}_1 \bar{\mathbf{x}}_1 = \bar{\mathbf{b}}_1 \quad (24)$$

$$\hat{\mathbf{D}}_2 \bar{\mathbf{x}}_2 = \bar{\mathbf{b}}_2 \quad (25)$$

$\vdots$

$$\hat{\mathbf{D}}_n \bar{\mathbf{x}}_n = \bar{\mathbf{b}}_n \quad (26)$$

$$\bar{\mathbf{x}}_1, \bar{\mathbf{x}}_2, \dots, \bar{\mathbf{x}}_n \geq 0, \quad (27)$$

where $\hat{\mathbf{D}}_1, \dots, \hat{\mathbf{D}}_n$ represent block matrices, and $\bar{\mathbf{b}}_1, \dots, \bar{\mathbf{b}}_n$, $\bar{\mathbf{c}}_1, \dots, \bar{\mathbf{c}}_n$, and $\bar{\mathbf{x}}_1, \dots, \bar{\mathbf{x}}_n$ represent vectors of appropriate dimension. Equations (23)–(27) can be easily decomposed into n subproblems involving $\bar{\mathbf{x}}_1, \bar{\mathbf{x}}_2, \dots, \bar{\mathbf{x}}_n$, and solved independently. The sum of the subproblem solutions will give the optimal value to Equation (23). Now consider problems that have the following structure:

$$\min \bar{\mathbf{c}}_1^\top \bar{\mathbf{x}}_1 + \bar{\mathbf{c}}_2^\top \bar{\mathbf{x}}_2 + \cdots + \bar{\mathbf{c}}_n^\top \bar{\mathbf{x}}_n \quad (28)$$

$$\text{s.t. } \hat{\mathbf{A}}_1 \bar{\mathbf{x}}_1 + \hat{\mathbf{A}}_2 \bar{\mathbf{x}}_2 + \cdots + \hat{\mathbf{A}}_n \bar{\mathbf{x}}_n = \bar{\mathbf{b}}_0 \quad (29)$$

$$\hat{\mathbf{D}}_1 \bar{\mathbf{x}}_1 = \bar{\mathbf{b}}_1 \quad (30)$$

$$\hat{\mathbf{D}}_2 \bar{\mathbf{x}}_2 = \bar{\mathbf{b}}_2 \quad (31)$$

$\vdots$

$$\hat{\mathbf{D}}_n \bar{\mathbf{x}}_n = \bar{\mathbf{b}}_n \quad (32)$$

$$\bar{\mathbf{x}}_1, \bar{\mathbf{x}}_2, \dots, \bar{\mathbf{x}}_n \geq 0, \quad (33)$$

where $\hat{\mathbf{A}}_1, \dots, \hat{\mathbf{A}}_n$ also represent block matrices. The constraint structure presented in Equations (28)–(33) is quite common for many practical problems. For example, problems in production, finance, and transportation often involve models where some subset of constraints only pertain to particular elements/areas of the problem (e.g., time periods) and others span the whole problem domain (e.g., all time periods). For such instances, *Dantzig–Wolfe decomposition* is an efficient solution approach [6,7,10]. Similar to the methods described earlier, Dantzig–Wolfe decomposition forms a master problem of the system in Equations

(28)–(33), which contains a basis. Then, the method uses a subproblem to generate admissible columns to add to the master problem, which is re-solved until no further improvement can be made with respect to the objective function. First, the master problem is formed by defining

$$\chi_i = \left\{ \hat{\mathbf{D}}_i \bar{\mathbf{x}}_i = \bar{\mathbf{b}}_i, \bar{\mathbf{x}}_i \geq 0 \right\} \quad \forall i = 1, \dots, n, \quad (34)$$

and assuming $\chi_i \neq \emptyset \forall i = 1, \dots, n$, Equations (28)–(33) become

$$\min \sum_{i=1}^n \bar{\mathbf{c}}_i^\top \bar{\mathbf{x}}_i \quad (35)$$

$$\text{s.t. } \sum_{i=1}^n \hat{\mathbf{A}}_i \bar{\mathbf{x}}_i = \bar{\mathbf{b}}_0 \quad (36)$$

$$\bar{\mathbf{x}}_i \in \chi_i, \quad \forall i = 1, \dots, n. \quad (37)$$

Then, using the *representation theorem* [6,7,10], we have that any element $\bar{\mathbf{x}}_i \in \chi_i$ can be expressed as

$$\bar{\mathbf{x}}_i = \sum_{q \in Q_i} \lambda_i^q v_i^q + \sum_{k \in K_i} \mu_i^k d_i^k, \quad (38)$$

where $v_i^q \forall q \in Q_i$ consist of the set of extreme points in χ_i and $d_i^k \forall k \in K_i$ is the set of extreme rays in χ_i ; also note that $\lambda_i^q \geq 0$, $\mu_i^k \geq 0$, and $\sum_{q \in Q_i} \lambda_i^q = 1 \forall i = 1, \dots, n$. Therefore, from the representation theorem Equations (35)–(37) are equivalent to

$$\min \sum_{i=1}^n \left(\sum_{q \in Q_i} \bar{\mathbf{c}}_i^\top (\lambda_i^q v_i^q) + \sum_{k \in K_i} \bar{\mathbf{c}}_i^\top (\mu_i^k d_i^k) \right) \quad (39)$$

$$\text{s.t. } \sum_{i=1}^n \left(\sum_{q \in Q_i} \hat{\mathbf{A}}_i (\lambda_i^q v_i^q) + \sum_{k \in K_i} \hat{\mathbf{A}}_i (\mu_i^k d_i^k) \right) = \bar{\mathbf{b}}_0 \quad (40)$$

$$\sum_{q \in Q_i} \lambda_i^q = 1, \quad \forall i = 1, \dots, n, \quad (41)$$

$$\lambda_i^q \geq 0, \quad \forall i = 1, \dots, n, q \in Q_i, \quad (42)$$

$$\mu_i^k \geq 0, \quad \forall i = 1, \dots, n, k \in K_i, \quad (43)$$

which is the master problem of Dantzig–Wolfe decomposition. One of the key issues with the master problem is that Equations (39)–(43) typically contain more variables than the original problem in Equations (28)–(33), since a variable is created for every extreme point and extreme ray of each polyhedron $\chi_i \forall i = 1, \dots, n$. This issue can be re-solved by using column generation methods (described in the section titled “Column Generation”) to facilitate the increased number of variables. For further discussion on the Dantzig–Wolfe algorithm the reader may refer to Refs 6–8 and 10.

Taking the dual of Equations (28)–(33) forms a problem that can be solved using *Benders decomposition*. Such problems describe the structure of a two-stage stochastic linear program and can be found in many practical models where uncertainty is present. Benders decomposition is a Dantzig–Wolfe decomposition algorithm applied to the dual, and, hence, the master problem contains many constraints. The key idea in Benders decomposition is to solve a relaxed master problem similar to what was done in cutting-plane methods, described in the section titled “cutting-Plane Methods”. For more information on Benders decomposition one may refer to Refs 6–8 and 10.

ROUTE BALANCING EXAMPLE

In this section, we present an example of an LP formulation to balance the routes for road crews used by street sweepers. Several counties across California have begun to switch from diesel-powered street sweepers to compressed natural gas (CNG) street sweepers in order to comply with Federal and State air quality regulations. However, due to a number of reasons, which include slow refueling time at CNG fueling stations and some design characteristics of the CNG sweepers, the productivity of the sweeping operations have decreased with these new sweepers.

The goal of the study is to identify new operating policies to improve the productivity of the CNG street sweepers. From a recent analysis of the assigned road miles, it was evident that the workload varied significantly

from crew to crew. Hence, a better balance of the assigned miles-to-crews could significantly improve the productivity of the crews. In this section, we present a mathematical model that optimizes the assignment of road miles to crews.

Input Parameters:

Let,

- $1, 2, \dots, n$: be the possible road crews with a total of n ;
- r_{ij} : be the maximum possible road miles that crew i can shift to crew j , $\forall i = 1, 2, \dots, n, j = 1, 2, \dots, n$, where $r_{ii} = 0$;
- a_i : be the original assigned miles of crew $i = 1, 2, \dots, n$;
- u : be the average miles of the region.

Decision Variables:

Let,

- x_{ij} : be the road miles that crew i shifts to crew j , $\forall i = 1, 2, \dots, n, j = 1, 2, \dots, n$, where $x_{ii} = 0$;
- z_i : be the deviation between the workload of crew $i = 1, 2, \dots, n$ and u .

Using the variable and parameter definitions above, the road crew linear program is as follows:

$$\min \sum_{i=1}^n z_i \quad (44)$$

$$\begin{aligned} \text{s.t.} \quad & \sum_{j=1}^n x_{ji} + a_i - \sum_{j=1}^n x_{ij} - u \leq z_i \\ & \forall i = 1, 2, \dots, n, \\ & \sum_{j=1}^n x_{ij} - a_i - \sum_{j=1}^n x_{ji} + u \leq z_i \end{aligned} \quad (45)$$

$$\forall i = 1, 2, \dots, n, \quad (46)$$

$$x_{ij} \leq r_{ij}$$

$$\forall i = 1, 2, \dots, n, j = 1, 2, \dots, n, \quad (47)$$

$$x_{ij} \geq 0$$

$$\forall i = 1, 2, \dots, n, j = 1, 2, \dots, n. \quad (48)$$

The objective in problem (44)–(48) is to minimize the deviation between the assigned miles of each crew and the average miles of the region, which is equivalent to

$$\sum_{i=1}^n \left| \sum_{j=1}^n x_{ji} + a_i - \sum_{j=1}^n x_{ij} - u \right|. \quad (49)$$

Here, variable z_i is used to represent the deviation and linear transformations represented by constraints (45) and (46). The objective function is simply the sum of the deviation of all crews. The smaller the objective value, the more balanced the routes are, and an objective value of zero means that each route in the region has exactly the same number of miles. The third constraint (47) limits the miles that crew i can shift to another crew. The data establishment of r_{ij} is based on the physical connection between two adjacent crews, since we only allow the reassignment of miles if the two crews are next to each other on the free-way. The last constraint (48) is simply a sign restriction on the nonnegativity of variable x_{ij} . The nonnegativity of variable z_i has already been ensured by the first and second constraints.

On the basis of the LP in Equations (44)–(48), we constructed an example that consists of 37 crews ($n = 37$) and has 31.25 miles average for the region ($u = 31.25$ miles). The resulting LP model contains 1406 variables and 2812 constraints, which can be easily increased in size. Thus, Equations (44)–(48) may be solved using cutting-plane methods or taking the dual and applying column generation. In addition, the problem used preassigned miles for

Table 1. Crew Road Miles

Crew	Current Solution (miles)	Optimized Solution (miles)
1	20.90	31.25
2	30.6	29.01
3	39.76	31.25
4	10.30	10.13
5	28.57	31.25

11	41.03	34.03
12	12.64	19.64
13	9.2	15.11
14	22.96	18.13
15	18.98	31.25
16	28.15	25.59
17	20.21	23.64
18	29.45	31.25
19	19.63	12.82
20	19.36	21.40
21	39.48	33.05
22	30.16	31.25
23	40.32	31.25
24	21.77	11.71
25	28.79	31.25
26	20.49	31.25
27	20.23	28.13
28	25.84	31.25
29	35.99	31.25
30	47.22	38.65
31	27.36	33.55
32	31.67	31.25
33	44.11	38.34
34	54.2	77.04
35	57.39	31.25
36	38.04	38.04
37	27.95	31.25

road crews; however, using column generation, alternative road-mile combinations may be generated—as presented in the section titled “Column Generation”. For the given example, Table 1 lists the assigned miles to each crew for the current and optimized solutions, which was solved using CPLEX 9.0. The optimal solution is 273.00 miles, which is a 29.39% improvement over the current actual practice of 386.64 miles.

Systems Engineering, Raleigh,
North Carolina

INTRODUCTION

Lévy processes, now widely used to construct and analyze financial models, were named in honor of the French mathematician *Paul Lévy* (1886–1971). As one of the founders of modern probability theory, Lévy made major contributions to the study of Gaussian processes, stable laws, infinitely divisible distributions, and processes with independent and stationary increments, which is now known as *Lévy processes*.

Lévy processes provide ingredients for building a rich class of continuous-time stochastic processes, such as *Poisson processes* and *Brownian motions*, which are two fundamental examples. For more details, see [1] and Chapter 5 of [2]. The applications of Lévy processes have immensely been emerging in many areas, for instance, queuing theory and financial engineering.

In this review article, we intend to give an introductory lecture and provide fundamental results on Lévy processes. In the section titled “Preliminary,” we state preliminaries on probability theory and stochastic processes; in the section titled “Lévy Processes,” we formally introduce Lévy processes and their distributional properties; in the section titled “Examples of Lévy Processes,” we illustrate five important examples of Lévy processes; in the section titled “Poisson Random Measures,” we present *Poisson random measures* (PRMs), the building blocks of the pure-jump part of Lévy processes; in the sections titled “Lévy–Itô Decomposition” and

“Lévy–Khintchine Formula,” we introduce the two most important theorems: *Lévy–Itô decomposition* and *Lévy–Khintchine formula*; and finally in the section titled “Path Properties,” we introduce four kinds of Lévy processes distinguished by different path properties.

PRELIMINARY

Probability Space and Random Variables

Let the triplet $(\Omega, \mathcal{F}, \mathbb{P})$ denote a *probability space*, where $\mathcal{F}$ is the σ -field (σ -algebra) of the underlying *sample space* Ω , and $\mathbb{P} : \mathcal{F} \rightarrow [0, 1]$ is the *probability measure* associated. A *random variable* is a real-valued $\mathcal{F}$ -measurable function $X : \Omega \rightarrow \mathbb{R}$, where $\mathcal{F}$ -measurability means that for any set B in the Borel σ -field $\mathcal{B}$, we have $X^{-1}(B) \in \mathcal{F}$. Note that the random variable X induces a probability measure μ_X on $\mathbb{R}$, defined by $\mu_X(B) \equiv \mathbb{P}(X^{-1}(B)) \equiv \mathbb{P}(\{\omega \in \Omega : X(\omega) \in B\})$ for any Borel set B in $\mathcal{B}$.

Let $F_X(\cdot) \equiv \mathbb{P}(X \leq \cdot)$ and $F_X^c \equiv 1 - F_X$ be the *cumulative distribution function (CDF)* and *complement cumulative distribution function (CCDF)* of a random variable X . Two random variables X and Y are said to be *equal in distribution*, denoted by $X \stackrel{D}{=} Y$, if $F_X = F_Y$. Two random variables X and Y are said to be *independent*, denoted by $X \perp Y$, if $\mathbb{P}(X \leq x, Y \leq y) = \mathbb{P}(X \leq x)\mathbb{P}(Y \leq y)$ for all $x, y \in \mathbb{R}$. Given the independence, the distribution (induced measure) of $X + Y$ is given by convolution of measures, that is, $\mu_{X+Y} = \mu_X * \mu_Y$. $\mu_X * \mu_Y(A) \equiv \int_{\mathbb{R}} \mu_X(A - y)\mu_Y(dy)$, $A \in \mathcal{B}$ and $\mu_Y(dy) \equiv \mathbb{P}(\{\omega \in \Omega : y < Y(\omega) < y + dy\})$.

Let $\mathbb{E}[X] \equiv \int_{\Omega} X d\mathbb{P} = \int_{\mathbb{R}} x \mu_X(dx) = \int_{\mathbb{R}} x dF(x)$ be the *expectation* of X , provided that $\int_{\mathbb{R}} |x| dF(x) < \infty$. Note that, if two random variables X and Y are independent, we have $\mathbb{E}[XY] = \mathbb{E}[X]\mathbb{E}[Y]$.

Characteristic Functions

The *characteristic function (CF)* of a random variable X is defined by $\Psi_X(\theta) \equiv \mathbb{E}[e^{i\theta X}]$, with

$\theta \in \mathbb{R}$ and $i \equiv \sqrt{-1}$. It has the following properties: (i) $|\Psi_X(\theta)| \leq 1$; (ii) $\Psi_X(\theta)$ is real-valued if and only if X is symmetric; (iii) $\Psi_X(\theta)$ is Hermitian, that is, $\Psi_X(-\theta) = \overline{\Psi_X(\theta)}$; and (iv) $\mathbb{E}[X^n] = i^{-n} \frac{d^n}{d\theta^n} \Psi_X(\theta) \Big|_{\theta=0}$. Note that the CF uniquely determines the distribution of a random variable.

The independence among the random variables can be understood through their CFs. Namely, the random variables $X_1, \dots, X_n$ are independent if and only if

$$\mathbb{E} \left[e^{i \sum_{k=1}^n \theta_k X_k} \right] = \prod_{k=1}^n \Psi_{X_k}(\theta_k). \quad (1)$$

Counting Processes and Counting Measures

A *stochastic process* $\{X(t), t \geq 0\}$ defined on a probability space $(\Omega, \mathcal{F}, \mathbb{P})$ is a parameterized collection of random variables $\{X(t)\}_{t \geq 0}$, assuming values in $\mathbb{R}$, that is, $X : [0, \infty) \times \Omega \rightarrow \mathbb{R}$. For each fixed $\omega \in \Omega$, $\{X(t, \omega), t \geq 0\}$ a sample path of the process, is a deterministic function and, for each fixed $t \geq 0$, $X(t, \cdot)$ is a random variable. A *counting process* $\{N(t), t \geq 0\}$ is a stochastic process that counts the total number of events occurred, and thus must be (i) nonnegative; (ii) integer-valued; and (iii) nondecreasing. Note that to understand (iii), we interpret $N(t) - N(s)$ as the total number of events occurred within time interval $(s, t]$.

A *counting measure* can be viewed as an induced measure by the associated counting process. Let $0 \leq T_1 \leq T_2 \leq \dots$ be the sequence of the occurrence times of events. For a measurable set $A \subset [0, \infty)$, define the measure $M(\omega, A) \equiv \#\{i \geq 1, T_i(\omega) \in A\}$. Note that the measure $M(\omega, \cdot)$ depends on $\omega \in \Omega$; it is thus a *random measure*. More details on random measures will be discussed in the section titled “Poisson Random Measures.”

LÉVY PROCESSES

A *random walk*, sum of independent and identically distributed (IID) random variables, provides the simplest example of discrete-time stochastic processes. We hereby introduce the definition of *Lévy processes*, the continuous-time analogs of random walks.

Definition 1. [Lévy Processes]. A continuous-time process $\{X(t), t \geq 0\}$ is called a *Lévy process* if

- (i) $X(0) = 0$;
- (ii) it has *independent* increments, that is, $X(t_4) - X(t_3) \perp X(t_2) - X(t_1)$ for all $0 < t_1 < t_2 < t_3 < t_4$;
- (iii) it has *stationary* increments, that is, $X(t_2) - X(t_1) \stackrel{D}{=} X(t_2 - t_1)$ for all $0 < t_1 < t_2$;
- (iv) its path is *stochastically continuous*, that is, $\lim_{s \rightarrow t} \mathbb{P}(|X(t) - X(s)| > \epsilon) = 0$, for $\epsilon > 0$.

Note that the *stochastic continuity* condition in property (iv) does not imply that sample paths of Lévy processes are continuous. For instance, *Poisson processes*, special cases of Lévy processes, are pure-jump processes. Property (iv) serves to rule out the processes with discontinuities at deterministic times (known as the “calender effect”).

Infinite Divisibility

A distribution F of a random variable X is called *infinitely divisible* if there exists n IID random variables $Y_{n,1}, \dots, Y_{n,n}$ such that the sum $\sum_{i=1}^n Y_{n,i}$ follows distribution F for all $n \geq 2$.

Famous examples of infinitely divisible distributions are *Poisson*, *Gaussian*, and *Gamma*. A random variable X following the above distributions can be expressed by a sum of n IID random variables following the same distribution but with modified parameter (dependent on n). For instance, a Gaussian random variable $X \sim \mathcal{N}(\mu, \sigma^2)$ is equal in distribution to $\sum_{i=1}^n Y_i$, where $Y_1, \dots, Y_n$ are IID following $\mathcal{N}(\mu/n, \sigma^2/n)$. Other examples are *Pareto*, *lognormal*, *Cauchy*, *stable*, and *student* distributions.

Distributional Properties of Lévy Processes

Lévy processes possess the *infinitely divisible* property. Consider a fixed time $t > 0$, we have

$$X(t) = \sum_{k=1}^n Y_k^{(t)}, \text{ where } Y_k^{(t)} \equiv X\left(\frac{kt}{n}\right) - X\left(\frac{(k-1)t}{n}\right),$$

denotes the increment of the process in the interval $((k-1)t/n, kt/n]$, $1 \leq k \leq n$. The infinite divisibility of $X(t)$ easily follows by properties (ii) and (iii) of the definition of Lévy processes.

Following Equation (1) and the definition of infinite divisibility, the CF of $X(t)$ with $t = n$ can be written as

$$\Psi_{X(n)}(\theta) = \prod_{k=1}^n \Psi_{Y_k^{(n)}}(\theta) = (\Psi_{X(1)}(\theta))^n,$$

where the last equality holds as $Y_k^{(n)} \stackrel{D}{=} Y_1^{(n)} = X(n/n) = X(1)$. We can then easily extend the above argument from integer-valued t to all $t > 0$. Therefore, for all $t > 0$, we can write the CF

$$\Psi_{X(t)}(\theta) = (\Psi_{X(1)}(\theta))^t \equiv e^{-t\psi(\theta)},$$

where the function ψ is called the *characteristic exponent* (CE) of the Lévy process $\{X(t), t \geq 0\}$. As $\Psi_{X(1)}(\theta) = e^{\psi(\theta)}$, the distribution (law) of the whole process is determined solely by the CE ψ , or equivalently by the distribution of the random variable $X(1)$. It is not hard to prove that for a distribution F that is infinitely divisible, there exists a Lévy process $\{X(t), t \geq 0\}$ such that the $X(1)$ follows F .

EXAMPLES OF LÉVY PROCESSES

We next introduce some concrete examples of Lévy processes. Some of these examples are fundamental building blocks to construct general Lévy processes.

Poisson Processes

A Lévy process $\{N(t), t \geq 0\}$ is a *Poisson process* with rate $\lambda > 0$ if, for a fixed t , the random variable $N(t)$ follows Poisson distribution with mean λt , that is, the *probability mass function* (PMF) $\mathbb{P}(N(t) = k) = e^{-\lambda t}(\lambda t)^k / k!$, for $k = 0, 1, 2, \dots$

Poisson processes are pure-jump processes with positive unit jumps and are thus counting processes. The intertransition times between these jumps $T_1, T_2, \dots$ form a sequence of IID *exponential* distribution with rate λ , having a *probability density*

function (PDF) $f_{T_1}(x) = \lambda e^{-\lambda x} \mathbf{1}_{\{x \geq 0\}}$. The CE of a Poisson process with rate λ is given by

$$\psi(\theta) = \lambda(1 - e^{i\theta}). \quad (2)$$

Besides Lévy processes, Poisson processes are special cases of several other classical processes, such as *renewal processes* and *continuous-time Markov chains*.

Compound Poisson Processes

Given a Poisson process $\{N(t), t \geq 0\}$ and a sequence of IID random variables $\{\xi_i : i \geq 1\}$ that are independent with N , then the process $\{Y(t), t \geq 0\}$ with $Y(t) \equiv \sum_{i=1}^{N(t)} \xi_i$ is called a *compound Poisson process*. Compound Poisson processes generalize Poisson processes from unit jump sizes to general and random jump sizes. In general, compound Poisson processes are no longer counting processes because there may be negative jumps. Let G be the CDF of ξ_1 , which describes the sizes of the jumps.

The fact that compound Poisson processes have stationary and independent increments simply follows from those properties of Poisson processes. The CE is given by

$$\psi(\theta) = \lambda \int_{\mathbb{R}} (1 - e^{i\theta y}) dG(y). \quad (3)$$

Note that Equation (3) reduces to Equation (2) when the measure induced by ξ_1 degenerates to $\delta_1(\cdot)$, the dirac measure at point 1.

Brownian Motions

A Lévy process with continuous sample path (with probability 1) $\{W(t), t \geq 0\}$ is called a standard *Brownian motion* when, for a fixed t , the random variable $W(t) \sim \mathcal{N}(0, t)$, that is, $W(t)$ follows a Gaussian distribution with mean 0 and variance t . Let

$$X(t) \equiv a W(t) + b t. \quad (4)$$

Then $\{X(t), t \geq 0\}$ is called a *Brownian motion with drift*. It is obvious that $X(t) \sim \mathcal{N}(bt, a^2 t)$ with PDF

$$f_{X(t)}(x) = \frac{1}{\sqrt{2\pi a^2 t}} e^{-\frac{(x-bt)^2}{2a^2 t}}.$$

The CE of X is given by

$$\psi(\theta) = a^2\theta^2/2 - i\theta b. \quad (5)$$

Inverse Gaussian Processes

Regarding a standard Brownian motion with drift $\{X(t), t \geq 0\}$ defined in Equation (4) with $a = 1$ and $b > 0$, define the first passage time

$$\tau(t) \equiv \inf\{s > 0 : X(s) > t\}, \quad (6)$$

that is, the first time a Brownian motion crosses above the level $t \geq 0$. Then the process $\{\tau(t), t \geq 0\}$ is called an *inverse Gaussian process*.

We use the so-called *strong Markov* property of Brownian motions to show that $\{\tau(t), t \geq 0\}$ indeed is a Lévy process. Define $X^*(t) \equiv X(\tau(s) + t) - s$, then the new process $\{X^*(t), t \geq 0\}$, describing the evolution of the Brown motion after hitting level s , is equal in distribution to $\{X(t), t \geq 0\}$. The dynamics of X^* is also independent of $X(u)$ for $0 \leq u \leq \tau(s)$. For $0 \leq s < t$ let $\tau^*(t-s)$ be the first passage time (in the form of Equation (6)) of X^* at level $t-s$. We thus have that the remaining time to level t (given hitting s)

$$\begin{aligned} \tau(t) - \tau(s) &= \tau^*(t-s) \stackrel{\mathcal{D}}{=} \tau(t-s) \\ \text{and } \tau(t) - \tau(s) &\perp \tau(s), \end{aligned}$$

which prove that the inverse Gaussian process has stationary and independent increments.

The PDF of $\tau(t)$ is given by

$$f_{\tau(t)}(x) = \frac{t}{\sqrt{2\pi x^3}} e^{tb} e^{-\frac{1}{2}(t^2 x^{-1} + b^2 x)},$$

and the CE takes the form

$$\psi(\theta) = \sqrt{-2i\theta + b^2} - b.$$

Furthermore, the inverse Gaussian process is an example of a *subordinator*, a subclass of Lévy processes having nondecreasing paths (see section titled “Path Properties”).

Stable Processes

A random variable Y is said to follow a *stable* distribution if, for all $n \geq 1$,

$$n^{1/\alpha} Y + b_n \stackrel{\mathcal{D}}{=} \sum_{i=1}^n Y_i, \quad (7)$$

where $Y_1, \dots, Y_n$ are IID copies of Y , $\alpha \in (0, 2]$ and $b_n \in \mathbb{R}$. We say the distribution is *strictly stable* if $b_n = 0$. By subtracting b_n/n from each term of the right-hand side of Equation (7) and divide both sides by $n^{1/\alpha}$, one can easily verify that stable distributions are infinitely divisible. *Stable processes* thus form one class of Lévy processes whose CEs correspond to those of stable distributions.

We point out that the case $\alpha = 2$ corresponds to zero mean Gaussian random variables. For $\alpha \in (0, 2)$, CE has the form

$$\begin{aligned} \psi(\theta) &\equiv c|\theta|^\alpha \Gamma(\theta, \alpha, \beta) + i\theta\eta, \quad \text{where} \\ \Gamma(\theta, \alpha, \beta) &\equiv \begin{cases} 1 - i\beta \tan(\frac{\pi\alpha}{2}) \text{sgn}(\theta), & \text{if } \alpha \neq 1, \\ 1 + i\beta \frac{2}{\pi} \text{sgn}(\theta) \log|\theta|, & \text{if } \alpha = 1, \end{cases} \end{aligned}$$

where $-1 \leq \beta \leq 1$, $c > 0$, $\eta \in \mathbb{R}$ and the sign function $\text{sgn}(x) \equiv \mathbf{1}_{\{x > 0\}} - \mathbf{1}_{\{x < 0\}}$.

POISSON RANDOM MEASURES

Because Poisson and compound Poisson processes play important roles in the construction of Lévy processes, we next introduce the concept PRM that is exploited to study the jump structure of Lévy processes.

Definition 2. [Poisson Random Measure]. Consider a probability space $(\Omega, \mathcal{F}, \mathbb{P})$ and $E \subset \mathbb{R}^d$. Given a Radon measure μ (i.e., $\mu(A) < \infty$ for any compact set A). A PRM on E with intensity measure μ is an integer-valued random measure such that

- (i) for $\omega \in \Omega$, $M(\omega, \cdot)$ is an integer-valued Radon measure on E ;
- (ii) for each measurable set $A \subset E$, $M(A) \equiv M(\cdot, A)$ is a Poisson random variable with mean $\mu(A)$;

- (iii) for disjoint measurable sets $A_1, \dots, A_n$, $M(A_1), \dots, M(A_n)$ are independent Poisson random variables.

We can construct a PRM with any given μ . Assume $\mu(E) < \infty$ without loss of generality, we (i) first generate IID random variables $X_1, X_2, \dots$ with $\mathbb{P}(X_i \in A) = \frac{\mu(A)}{\mu(E)}$; (ii) second generate an independent Poisson random variable $M(E)$ on $(\Omega, \mathcal{F}, \mathbb{P})$ with mean $\mu(E)$; (iii) and finally let $M(A) \equiv \sum_{i=1}^{M(E)} \mathbf{1}_{\{X_i \in A\}}$.

Constructing Jump Processes Using PRM

PRMs can be employed to construct jump processes. Consider $E = [0, T] \times \mathbb{R} \setminus \{0\}$, we can write

$$M = \sum_{n \geq 1} \delta_{(T_n, \xi_n)}, \quad \text{or} \quad M(E) = \sum_{n \geq 1} \mathbf{1}_{\{(T_n, \xi_n) \in E\}},$$

where $(T_n)_{n \geq 1}$ is an increasing sequence. Each point $[T_n(\omega), \xi_n(\omega)] \in [0, T] \times \mathbb{R} \setminus \{0\}$ corresponds to jump with size $\xi_n(\omega)$ at time $T_n(\omega)$. The second expression counts the total number of jumps in $[0, T]$. We hereby exclude 0 so that every jump has a nonzero size.

By integrating a measurable function f with respect to the PRM M , we can construct a jump process

$$\begin{aligned} X(t) &= \int_0^t \int_{\mathbb{R} \setminus \{0\}} f(s, y) M(ds \times dy) \\ &= \sum_{T_n \in [0, t]} f(T_n, \xi_n), \end{aligned}$$

The above jump process becomes the compound Poisson process introduced in the section titled “Examples of Lévy Processes” when $f(s, y) = y$ and $\mu(ds \times dy) = \lambda \mu_{\xi_1}(dy)ds$, where μ_{ξ_1} is the measure induced by ξ_1 . It becomes a Poisson process when $\mu_{\xi_1} = \delta_1$, see section titled “Examples of Lévy Processes.”

LÉVY–ITÔ DECOMPOSITION

We are now ready to present the most fundamental result of Lévy processes, the *Lévy–Itô*

decomposition. The Lévy–Itô decomposition enables us to understand the path structures of a general Lévy process by decomposing the Lévy process into three independent auxiliary Lévy processes.

Consider a Lévy process $\{X(t), t \geq 0\}$. We let $\Delta X(t) \equiv X(t+) - X(t-)$ be the size of a jump, if any, at time t and let A be a measurable set in $\mathbb{R}$. A *jump measure* is defined by

$$M_X(B) \equiv \#\{[t, \Delta X(t)] \in B\}, \quad (8)$$

for a measurable set $B \subset [0, \infty) \times \mathbb{R}$. Note that $M_X([t_1, t_2] \times A)$ counts the number of jumps of the Lévy process X in $[t_1, t_2]$ with jump sizes in A . The *Lévy measure* associated with X is defined as

$$\nu_X(A) \equiv \mathbb{E} \left[\sum_{0 \leq t \leq 1} \mathbf{1}_{\{\Delta X(t) \neq 0, \Delta X(t) \in A\}} \right], \quad (9)$$

which describes the expected number of jumps with sizes in A , per unit time. Obviously, we have

$$\nu_X(A) = \mathbb{E}[M_X([0, 1] \times A)]. \quad (10)$$

Lévy–Itô Decomposition

A Lévy process $\{X(t), t \geq 0\}$ can be written as

$$X(t) = X^c(t) + X^l(t) + X^s(t), \quad (11)$$

where $X^c(t)$, $X^l(t)$, and $X^s(t)$ are three independent processes; $X^c(t) \equiv bt + aW(t)$ is a Brownian motion with drift as defined in Equation (4); the two terms $X^l(t)$ and $X^s(t)$ are defined by

$$X^l(t) \equiv \int_0^t \int_{|x| \geq 1} x M_X(du \times dx) \quad (12)$$

and

$$X^s(t) \equiv \lim_{\epsilon \rightarrow 0} \int_0^t \int_{\epsilon \leq |x| < 1} x \tilde{M}_X(du \times dx), \quad (13)$$

with $\tilde{M}_X(du \times dx) \equiv M_X(du \times dx) - \nu_X(dx)du$ being the centered (compensated) version of the jump measure M_X , as defined in

Equation (8); the Lévy measure ν_X , as defined in Equation (9), is a Radon measure on $\mathbb{R} \setminus \{0\}$ such that

$$\int (|y|^2 \wedge 1) \nu_X(dy) < \infty; \quad (14)$$

and $a, b \in \mathbb{R}$ are constants.

To better understand this important result, we remark on the meanings of the three terms of the right-hand side in Equation (11). First, the Brownian motion with drift $X^c(t)$, described by the drift b and volatility term a , characterizes the continuous part of the path of a Lévy process.

The second term in Equation (11), as elaborated in Equation (12), is a compound Poisson process with a finite number of jumps with size > 1 . Note that the finiteness here is guaranteed by condition Eq. (14). Here the threshold separating big jumps and small jumps is set to be 1 as a convention. Changing the threshold from 1 to an arbitrary constant $c > 0$ results in a refinement of the drift term b . See [3] for alternative representations with a general c .

Finally, as the measure ν_X may have a singularity at 0, there can be infinitely many small jumps whose sum does not necessarily converge. This prevents us from letting ϵ go to 0 directly for a compound Poisson process with amplitude between ϵ and 1. The third term in Equation (11), as elaborated in Equation (13), thus has to be centered by the measure $\nu_X(dx)du$ to obtain convergence.

In summary, the Lévy–Itô decomposition implies that an arbitrary Lévy process can be decomposed into the sum of three independent components: (i) a Brownian motion with drift, (ii) a compound Poisson process with finite and big jumps, and (iii) a discontinuous process with an infinite number of small jumps. The distribution of a Lévy process is thus characterized by three parameters a , b , and ν_X .

LÉVY–KHINTCHINE FORMULA

Using the Lévy–Itô decomposition, we can quickly obtain the second fundamental result: the *Lévy–Khinchine formula*.

Lévy–Khinchine Formula

Consider a Lévy process $\{X(t), t \geq 0\}$ with parameter (a, b, ν_X) , its CE has the form

$$\begin{aligned} \psi(\theta) = & \left(\frac{1}{2} a^2 \theta^2 - i b \theta \right) + \int_{|x| \geq 1} (1 - e^{i \theta x}) \nu_X(dx) \\ & + \int_{|x| < 1} (1 - e^{i \theta x} + i \theta x) \nu_X(dx). \end{aligned} \quad (15)$$

This result can be quickly proved using the Lévy–Itô decomposition and Equation (1). It can be easily seen from Equations (5) and (3) that the first two terms of the right-hand side of Equation (15) are the CE's of a Brownian motion with drift and a compound Poisson process with jump amplitudes greater than 1, corresponding to the first two terms of the right-hand side in Equation (11). In addition, the third term in Equation (15) is the CE of Equation (13).

PATH PROPERTIES

In the section titled “Lévy–Itô Decomposition,” the distribution of a Lévy process $\{X(t), t \geq 0\}$ is characterized by its parameters a , b , and ν_X . We now introduce four typical kinds of Lévy processes distinguished by different path properties, reflected by different parameters.

Continuous Paths

As both X^l and X^s in Equation (11) represent jumps, a Lévy process having a continuous sample path must be a Brownian motion with drift. As a result, we must have only the first term in Equation (11) with $\nu_X = 0$ and Equation (15) thus degenerates to Equation (5).

Piecewise Constant Paths

On the contrary, as X^c in Equation (11) represents the continuous part, a pure-jump Lévy process (thus having piecewise constant paths) must be a compound Poisson process. Hence, the Lévy process involves only the second two terms in Equation (11) with $a = b = 0$ and $\nu_X(\mathbb{R}) < \infty$, see Ref. 4 for more details. Consequently, Equation (15) thus

degenerates to Equation (3) with $\nu_X(dx) = \lambda dG(x)$.

Finite Variation

Consider an interval $[0, T]$, a function f is said to be of *finite variation* if, for each partition $0 = t_0 < t_1 < \dots < t_{n-1} < t_n = T$, the total variation thereof is finite, that is,

$$TV(f, [0, T]) \equiv \sup_{\{t_k\}_{k=1}^n} \sum_{i=1}^n |f(t_i) - f(t_{i-1})| < \infty.$$

As Brownian motions have infinite variation over any finite interval [5], a Lévy process with finite variation must not involve the Brownian term W , that is, we have $a = 0$ in Equation (15). In addition, as compound Poisson processes [denoted by X^I in Equation (12)] always have finite variation, we impose extra conditions such that X^s has finite variation. We require $\int_{|x| \leq 1} |x| \nu_X(dx) < \infty$. In this case, Equation (11) simplifies to

$$X(t) = \tilde{b}t + \int_0^t \int_{x \in \mathbb{R}} x M_X(du \times dx),$$

$$\text{where } \tilde{b} \equiv b - \int_{|x| < 1} x \nu_X(dx).$$

Subordinators

A Lévy process having nondecreasing paths over time is called a *subordinator*. In this case, the Brownian term is again not involved because the path of a Brownian motion is not monotone. Hence, $a = 0$. In addition, we require the Lévy process to have merely positive jumps of finite variation and positive drift, that is, $\nu_X((-\infty, 0]) = 0$, $\int (x \wedge 1) \nu_X(dx) < \infty$ and $b \geq 0$. See Ref. 3 for more discussion on subordinators.

FURTHER READING

More detailed contents on Lévy processes can be referred to the following books [3, 4, 6–8]. Readers who are interested in infinite divisibility properties are referred to [9]. Regarding applications of Lévy processes in queuing theory, we refer to the book [10] and a recent survey on Lévy-driven queues [11].

INTRODUCTION TO MULTIATTRIBUTE UTILITY THEORY

JOHN C. BUTLER
and JAMES S. DYER
McCombs School of Business,
University of Texas at Austin,
Austin, TX

INTRODUCTION

In this article, we provide a review of multiattribute utility (MAU) theory. We begin with a brief review of single-attribute utility theory, and explore preference representations that measure a decision maker's preferences for risky alternatives. Following convention (Keeney and Raiffa, 1993),¹ we adopt the term utility function for preferences in risky situations and use the term value function for preferences measured based on ordinal comparisons and strength of preference. Next, we characterize the multiattribute decision problem, and discuss the conditions that allow a MAU function to be decomposed into three common functional forms. Finally, the relationships between multiattribute preference functions under conditions of certainty and risk are discussed, and we survey issues related to their assessment and applications.

MAU theory provides an axiomatic foundation for choices involving multiple criteria. As a result, one can examine these axioms and determine whether or not they are reasonable guides to rational behavior. Often arguments are made that decision makers do not always make decisions that are consistent with these axioms, and, therefore, the axioms should not be viewed as necessary for a theory of choice. While this may be

true as a descriptive statement for individual decision-making, it is much more difficult to identify situations involving significant implications for other parties where a cavalier disregard for normative theories of choice can be defended. Further, theories that do not provide consistent recommendations can be compared on first principles by evaluating the underlying axioms.

UTILITY THEORY: PREFERENCE REPRESENTATIONS UNDER RISK

Utility theory studies the fundamental aspects of individual choice behavior, such as how to identify and quantify an individual's preferences over a set of alternatives, and how to construct appropriate preference representation functions for decision-making under risk. An important feature of utility theory is that it is based on rigorous axioms, which characterize an individual's choice behavior. These preference axioms are essential for establishing preference representation functions, and provide the rationale for the quantitative analysis of preference.

Utility theory is primarily concerned with properties of a binary preference relation $\succ$ on a choice set P , where P is a convex set of probability distributions or lotteries $\{p, q, r, \dots\}$ on a nonempty set X of outcomes. As an example, we might present an individual with a pair of alternatives, say p and q (e.g., two gambles with one nonzero outcome from the set X of monetary values) where $p, q \in P$ (e.g., the set of all monetary gambles with one nonzero outcome), and ask how they compare (e.g., do you prefer p or q ?). For example, p could be a fair coin flip that pays \$10 for heads and \$0 for tails and q could be a fair die roll that pays \$12 for a number larger than 4 and \$0 otherwise. If the individual says that p is preferred to q , then we write $p \succ q$, where $\succ$ means strict preference. If the individual states that he or she is indifferent between p and q , then we represent this preference as $p \sim q$. Alternatively, we can define $\sim$ as the absence of strict preference; that is, not $p \succ$

¹*Decisions with Multiple Objectives* by R. L. Keeney and H. Raiffa was originally published by Wiley in 1976. The Cambridge University Press version was published in 1993.

q and not $q > p$. If it is not the case that $q > p$, then we write $q \succsim p$, where $\succsim$ represents a weak preference (or preference-indifference) relation. We can also define $\succsim$ as the union of strict preference $>$ and indifference $\sim$; that is, both $q > p$ and $p \sim q$.

Preference studies begin with some basic assumptions (or axioms) of individual choice behavior. First, it seems reasonable to assume that an individual can state preference over a pair of alternatives without contradiction; that is, the individual does not strictly prefer p to q and q to p simultaneously. This leads to the following definition for *preference asymmetry*: preference is asymmetric if there is no pair p and q in P such that $p > q$ and $q > p$. In other words, asymmetry ensures preference consistency.

Furthermore, if an individual makes the judgment that p is preferred to q , then he or she should be able to place any other alternative r somewhere on the ordinal scale determined by the following: either better than q or worse than p , or both. Formally, we define *negative transitivity* by saying that preferences are negatively transitive if given $p > q$ in P and any third element r in P , it follows that either $p > r$ or $r > q$, or both.

If the preference relation $>$ is asymmetric and negatively transitive, then it is called a *weak order*. The weak order assumption implies some desirable properties of a preference ordering and is a basic assumption in many preference studies. If the preference relation $>$ is a weak order, then the associated indifference and weak preference relationships are well behaved. More specifically, if strict preference $>$ is a weak order, then

1. strict preference $>$ is *transitive* (if $p > r$ and $r > q$, then $p > q$);
2. indifference $\sim$ is *transitive*, *reflexive* ($p \sim p$ for all p); and *symmetric* ($p \sim q$ implies $q \sim p$);
3. exactly one of $p > q$, $q > p$, or $p \sim q$ holds for each pair p and q ; and
4. weak preference $\succsim$ is *transitive* and *complete* (for a pair p and q , either $p \succsim q$ or $q \succsim p$).

Thus, an individual whose strict preference can be represented by a weak order can specify a unique ranking of all alternatives under consideration. Further discussions of the properties of binary preference relations are presented in Refs 1 and 2.

Perhaps the most significant contribution to the theory of risky choice was the formalization of *expected utility theory* by von Neumann and Morgenstern [3]. This development has been refined by a number of scholars and is most commonly presented in terms of three basic axioms [1].

For lotteries p, q, r in P and all $\lambda, 0 < \lambda < 1$, the expected utility axioms are:

1. *Ordering*: $>$ is a weak order;
2. *Independence*: If $p > q$, then $(\lambda p + (1-\lambda)r) > (\lambda q + (1-\lambda)r)$ for all $r \in P$;
3. *Continuity*: If $p > r > q$, then there exist some $0 < \alpha < 1$ and $0 < \beta < 1$ such that $(\alpha p + (1-\alpha)q) > r > (\beta p + (1-\beta)q)$.

The von Neumann-Morgenstern expected utility theory asserts that the above axioms hold if and only if there exists a real-valued function u defined on the set X of outcomes such that for all p, q in P , $p > q$ if and only if

$$\sum_{x \in X} p(x)u(x) \geq \sum_{x \in X} q(x)u(x)$$

where $p(x)$ and $q(x)$ are the probabilities of outcome x for lotteries p and q , respectively. Moreover, such a u is unique up to a positive linear transformation.

The expected utility model can also be used to characterize an individual's risk attitude (Chapter 4, [4, 5]). If an individual is indifferent between the expected value of a lottery and the lottery itself, then we say that the individual is risk neutral. Intuitively, the "risk" associated with the gamble does not have an impact on this individual's preferences, and, therefore, he or she perceives the value of the risky alternative to be equal to its actuarial expected value. However, if he or she feels that his or her subjective assessment of the value of the lottery, known as his or her certainty equivalent for the lottery, is less than its expected value, then we say that he or she is risk averse. Conversely,

Figure 1. Example single-attribute utility function shapes.

if he or she feels that his or her certainty equivalent for the lottery is more than its expected value, we say that he or she is risk seeking.

A utility function defined on the outcome set X may be plotted on any arbitrary scale, but typically the range from 0 to 1 is used. If an individual is risk averse, risk neutral, or risk seeking over the range of X , then the individual's utility function is concave, linear, or convex, respectively. Examples of these utility function shapes are shown in Fig. 1.

The von Neumann-Morgenstern theory of risky choice presumes that the probabilities of the outcomes of lotteries are provided to the decision maker. Savage [6] extended the theory of risky choice to allow for the simultaneous determination of subjective probabilities for outcomes and a utility function u defined over those outcomes. The probabilities in Savage's model are personal or subjective probabilities, and the model itself is a subjective expected utility representation.

The assessment of von Neumann-Morgenstern utility functions will almost always involve the introduction of risk in the form of simple lotteries. Two basic risky stimuli are shown in Fig. 2. In the certainty equivalent assessment method (left panel of Fig. 2), the decision maker is asked to provide a sure amount $\$X$ such that he or she is indifferent to receiving $\$X$ for sure and receiving the lottery that has an expected monetary value of $\$140$. A risk-neutral decision maker would specify $\$X = 140$; risk aversion would be consistent with $\$X < 140$ and a risk seeker would specify $\$X > 140$. The right panel of Fig. 2 depicts the probability equivalent

Figure 2. Utility function assessment examples.

method for utility assessment where the decision maker specifies a probability p that leads to equivalence between $\$150$ and the stimulus lottery. A risk-neutral decision maker would specify $p = 0.5$, whereas risk-averse (risk-seeking) utility functions would be consistent with $p > (<) 0.5$. To assess a utility function, these questions would be repeated for different stimuli that cover the range of dollar outcomes. For a more general discussion of these assessment approaches, see [5] or [7].

As a normative theory, the expected-utility model has played a major role in the prescriptive analysis of decision problems. However, for descriptive purposes, the assumptions of this theory have been challenged by empirical studies (e.g., [8]). Some of these empirical studies demonstrate that subjects may choose alternatives that imply a violation of the independence axiom. One implication of the independence axiom is that the expected utility model is "linear in probabilities." For a discussion, see Fishburn and Wakker [9]. A number of contributions have been made by relaxing the independence axiom and developing some *nonlinear utility models* to accommodate actual decision behavior [10–12].

MULTIATTRIBUTE UTILITY FUNCTIONS

Suppose that the outcomes defined for the preference functions are now considered to be vectors. That is, suppose that $X = X_1 \times X_2 \times \dots \times X_n$ where X_i represents the performance of an alternative on attribute i . In this section, we use the letters x , y , and z to indicate distinct elements of X . For example, $w \in X$ is represented by $(w_1, w_2, \dots, w_n)$, where w_i is a level in the nonempty attribute set X_i for $i = 1, \dots, n$. We let $I \subset \{1, 2, \dots, n\}$ be a subset of the attribute indices, define X_I as the subset of the attributes designated by the subscripts in I , and let $\bar{X}_I$ represent the complementary subset of the n attributes. We may write $w = (w_I, \bar{w}_I)$ or use the notations $(z_i, \bar{w}_i)$ and $(x_i, \bar{w}_i)$ to denote two elements of X that differ only in the level of the i th attribute. Finally, we also assume that the preference relation $\succsim$ on X is consistent with the expected-utility axioms 1–3, which means that there exists a von Neumann-Morgenstern utility function $u(x_1, x_2, \dots, x_n)$ defined on X .

If the decision maker's preferences are consistent with some additional independence conditions, then $u(x_1, x_2, \dots, x_n)$ can be decomposed into additive, multiplicative, and other well-structured forms that simplify assessment.

Preference Independence

The concept of mutual preference independence can be defined as follows:

1. X_I is *preference independent* of $\bar{X}_I$ if $(w_I, \bar{w}_I) \succ (x_I, \bar{w}_I)$ for any $w_I, x_I \in X_I$ and $\bar{w}_I \in \bar{X}_I$ implies $(w_I, \bar{x}_I) \succ (x_I, \bar{x}_I)$ for all $\bar{x}_I \in \bar{X}_I$.
2. The attributes $X_1, \dots, X_n$ are *mutually preference independent* if for every subset $I \subseteq \{1, \dots, n\}$ the set X_I of these attributes is preference independent of $\bar{X}_I$.

Attributes X_i and X_j are preference independent if the tradeoffs (substitution rates) between X_i and X_j are independent of all other attributes. Mutual preference independence requires that preference independence

holds for all pairs X_i and X_j . Essentially, mutual preference independence implies that the indifference curve for any pair of attributes is unaffected by the fixed levels of the remaining attributes. The indifference curve is the set of all combinations of X_i and X_j that have the same utility value when the other attributes are held constant and is typically plotted as a line or curve.

In practice, the condition of preference independence among a set of attributes is often a reasonable assumption. For example, suppose that a decision maker is choosing from a set of automobiles based on the attributes of cost, horsepower, and attractiveness. Further, assume that the decision maker prefers more horsepower to less, lower costs, and more attractive automobiles. If he or she prefers an automobile with the attribute values (\$25K, 170 hp, ugly) to one with the attribute values (\$28K, 200 hp, ugly), then if cost and horsepower are preference independent of appearance, he or she will still prefer the first set of attribute values to the second set if the appearance for both alternatives is changed to beautiful. This would also be true for the preference order of any two alternatives that differ in the first two attributes but have a common value for the third attribute.

Preference independence does imply the existence of an additive MAU function that exists in the case of certainty for the comparison of alternatives where there is no risk regarding any of the outcomes. However, the approaches that can be used to construct this additive function require tradeoffs by the decision maker among pairs of attributes in a manner that would be difficult to implement in practice (see [5], Sections 3.4.6 and 3.4.7). Nevertheless, mutual preference independence is an important concept because it can be combined with other independence conditions to allow a MAU function to be decomposed into a form that is easy to assess using much simpler expressions of preference by a decision maker.

Utility Independence

An attribute X_i is said to be *utility independent* of its complementary attributes if

preferences over lotteries with different levels of X_i do not depend on the fixed levels of the remaining attributes. Attributes $X_1, X_2, \dots, X_n$ are mutually utility independent if all proper subsets of these attributes are utility independent of their complementary subsets. Further, it can be shown that if these same attributes are mutually preference independent, then they will also be mutually utility independent if any pair of the attributes is utility independent of its complementary attributes [5].

Once again, suppose that a decision maker is choosing from a set of automobiles based on the attributes of cost, horsepower, and attractiveness, but now there is some uncertainty regarding new environmental laws that may impact the cost and the horsepower of a particular automobile. The current performance levels of one of the alternatives may be (\$25.0K, 170 hp, ugly), but if the legislation is passed a new device will have to be added that will increase cost and decrease horsepower leading to a new performance vector (\$25.7K, 150 hp, ugly). An alternative automobile might have possible outcomes of (\$28.0K, 200 hp, ugly) if the legislation does not pass and (\$29.0K, 175 hp, ugly) if it does. We will assume that a decision maker estimates the legislation will pass with probability 0.5.

Therefore, the decision maker is evaluating choices between lotteries such as the one shown in Fig. 3. For example, the decision maker may prefer Auto 1 to Auto 2, because the risks associated with the cost and the horsepower for Auto 1 are more acceptable to his or her than the risks associated with the cost and horsepower of Auto 2. If the decision maker's choices for these lotteries do not depend on common values of the third

attribute, then cost and horsepower are utility independent of appearance.

If the decision maker's preferences are such that each attribute is utility independent of its complimentary set of attributes, then these preferences may be represented by a MAU function $u(x_1, x_2, \dots, x_n)$ with the multilinear form

$$\begin{aligned} u(x) = & \sum_{i=1}^n k_i u_i(x_i) + \sum_{i=1}^n \sum_{j>i}^n k_{ij} u_i(x_i) u_j(x_j) \\ & + \sum_{i=1}^n \sum_{j>i}^n \sum_{m>j>i}^n k_{ijm} u_i(x_i) u_j(x_j) u_m(x_m) + \dots \\ & + k_{123\dots n} u_1(x_1) u_2(x_2) \dots u_n(x_n) \end{aligned} \quad (1)$$

where u_i is a single-attribute function over X_i scaled from 0 to 1, $0 < k_i < 1$ and k_{ijm} is a scaling constant that represents the impact of the interactions among attributes i, j , and m on preferences, for example [5]. These scaling constants are sometimes called *weights* on the criteria in the literature, but we will use the former term to avoid the implication that they reflect a "weight of importance" of a criterion, which would be misleading as we shall discuss.

If the stronger condition of mutual utility independence is consistent with the preferences of the decision maker, then the multiplicative model is appropriate

$$1 + k u(x_1, x_2, \dots, x_n) = \prod_{i=1}^n [1 + k k_i u_i(x_i)] \quad (2)$$

where k is the lone additional scaling constant, suggesting that the strength of all interactions is the same [5]. If the scaling constant k is determined to be 0 through the appropriate assessment procedure, then (2)

Figure 3. Choice between two lotteries.

reduces to the additive form

$$u(x_1, x_2, \dots, x_n) = \sum_{i=1}^n k_i u_i(x_i) \quad (3)$$

where $\sum_{i=1}^n k_i = 1$. To see this, expand the right hand side of (2), subtract 1 from both sides of the equation, and divide by λ .

Additive Independence

A majority of the applied work in multiattribute utility theory deals with the case when the von Neumann-Morgenstern utility function is decomposed into the additive form 3. As noted earlier, the additive form can be a special case of the multilinear utility function, and this can be determined through the assessment procedure for the scaling constants. However, it is useful to be able to determine the existence of this important form of the multiattribute utility function by directly testing the appropriate preference conditions.

Fishburn [13] has derived necessary and sufficient conditions for a utility function to be additive. The key condition for additivity is that the preferences for any lotteries $p, q \in P$ should depend only on the marginal probabilities of the attribute values and not on their joint probability distributions.

Returning to the automobile example once again, an additive utility model (3) will be appropriate if the decision maker is indifferent between the two lotteries shown in Fig. 4, and for all other permutations of the attribute values that maintain the same marginal probabilities for each.

Notice that in either lottery in Fig. 4, the marginal probability of receiving the most preferred outcome or the least preferred outcome on each attribute is identical (0.5). However, a decision maker may prefer Auto 2 over Auto 1 if he or she wishes to avoid a 0.5 chance of the poor outcome (\$29K, 150 hp, ugly) on all three attributes, or he or she may have the reverse preference if he or she is willing to accept some risk in order to have a chance at the best outcome on all three attributes. In either of the latter cases, utility independence may still be satisfied, and the

Figure 4. Additive independence criterion for risk.

multilinear 1 or the multiplicative 2 decomposition of the multiattribute utility function may be appropriate.

The assessment of the multiplicative (2) or additive form (3) implied by the condition of mutual utility independence is simplified by the fact that each of the single-attribute utility functions may be assessed independently (more accurately, while all of the other attributes are held constant at arbitrarily selected values), using the well-known utility function assessment techniques suitable for single-attribute utility functions. Other independence conditions have been identified that lead to more complex nonadditive decompositions of a multiattribute utility function. These general conditions are reviewed in Farquhar [14] and more recently in Abbas and Bell [15].

We present a hypothetical example of the assessment of an additive two-attribute utility model for a decision maker considering a car purchase based on the attributes of cost (x_c) and horsepower (x_h) using the attribute ranges of [\$25K, \$29K] for cost and (150 hp, 200 hp) for horsepower in the previous example. We have assumed a linear utility function for cost and a concave exponential utility function for horsepower, but these could be assessed using one of the processes described in Fig. 2 to determine utility function values at discrete points and then by fitting continuous functions to these points. Next, we detail how to assess the scaling constants for an additive utility function to

arrive at $u(x_c, x_h) = 0.625 u_c(x_c) + 0.375 u_h(x_h)$ as shown in Fig. 5.

Intuitively, the scaling constants of a multicriteria decision model are measures of the importance of the *increase* from the worst to the best level of performance on one objective compared to the *increase* from the worst to the best level of performance on another objective. For example, if one were planning to purchase a car from the set of cars with costs between \$10,000 and \$1,000,000, then cost would have relatively more influence on the decision than if we limit the choice set to the Honda Accord and the Mazda 626 so that the range of cost would be between \$25,000 and \$29,000. Other features of the cars would become more relevant when making the latter decision.

One of the common techniques for assessing the scaling constants is the tradeoff approach that explicitly considers the ranges over which the attributes vary. The tradeoff

approach begins by having the decision maker consider a pair of hypothetical alternatives. For example, he or she might be asked to compare the alternatives A and B shown below.

	Alternative A	Alternative B
Cost	\$25K	\$29K
Horsepower	150 hp	200 hp

Note that alternative A has the best level of cost and the worst level of horsepower, whereas the opposite is true for B. Often there are more than two criteria that determine the performance of an alternative. When this occurs, the decision maker is asked to imagine that A and B have identical outcomes on all other criteria.

Figure 5. Additive two-attribute model.

The decision maker is asked if he or she prefers one alternative to the other. If he or she is indifferent between the two alternatives, the scaling constant assessment for this particular pair of measures is complete and the attribute scaling constants are equal. Typically, he or she will prefer one alternative to another. For example, let us assume that alternative A is preferred. This implies that it is more important to shift cost from \$29K to \$25K than to shift horsepower from 150 to 200 hp. In other words, the scaling constant on cost is greater than the scaling constant on horsepower.

In this case, the decision maker is asked to provide x'_c such that alternative A is indifferent to alternative B:

	Alternative A	Alternative B
Cost	\$25K	x'_c
Horsepower	150 hp	200 hp

When indifference has been achieved, we know that

$$k_c u_c(\$25K) + k_h u_h(150) = k_c u_c(x'_c) + k_h u_h(200)$$

or

$$k_c [u_c(\$25K) - u_c(x'_c)] = k_h [u_h(200) - u_h(150)]. \quad (4)$$

For scaling purposes, we set the utility of the most preferred level of each alternative to 1 and the utility of the least preferred alternative to 0 and (4) reduces to

$$k_c [1 - u_c(x'_c)] = k_h [1 - 0] \quad (5)$$

Thus, the ratio of the scaling constant for cost to the scaling constant for horsepower is

$$k_c/k_h = 1/[1 - u_c(x'_c)] \quad (6)$$

Given our linear utility function for cost, $u_c(x_c) = (29 - x_c)/(29 - 25)$ as $u_c(x_c)$ is decreasing in x_c . If the decision maker indicates that

he or she would pay \$2.4K to shift horsepower from 150 to 200, then he or she has specified $x'_c = 25K + 2.4K = \$27.4K$. Hence, $u_c(27.4) = 0.4$, $k_c/k_h = 5/3$ and $k_c = 0.625$.

To see the impact of the range of performance on the relative importance of an attribute, assume that we decide to consider cars that cost up to \$50K rather than our initial assumption of a maximum price of \$29K. There is no reason that this change in the range should impact x'_c — it is still worth \$2.4K to increase the horsepower from worst to best—but it will affect $u_c(x'_c)$. Now, $u_c(x_c) = (50 - x_c)/(50 - 25)$, $u_c(27.4) \cong 0.904$, $k_c/k_h \cong 10.417$, and $k_c \cong 0.912$. As we suggested at the start, when the range of the cost of cars considered increases while the ranges of the other attributes are held constant, the scaling constant for cost increases. However, the additive utility function would still give the same ranking of the alternatives because the increase in the scaling constant for cost would be just offset by a decrease in the corresponding utility function score on cost, as x'_c would be a smaller proportion of the range of the utility function.

For a multiattribute problem with n criteria, $n-1$ tradeoffs will be required in order to determine $n-1$ equations in n unknowns. Using these ratios and the restriction that the sum of the scaling constants is unity, we can solve for all the scaling constants. See Keeney and Raiffa [5] or [16] for additional details and examples of scaling constant assessment.

VALUE FUNCTIONS: PREFERENCE FUNCTIONS FOR CERTAINTY

Keeney and Raiffa [5] emphasized the use of multiattribute preference models based on the theories of von Neumann and Morgenstern [3], which rely on axioms involving risk. As a result, this approach has become synonymous in the view of many scholars with multiattribute preference theory. However, this theory is not the appropriate one for decisions involving multiple objectives when the outcomes of the alternatives are known with certainty.

Single-Attribute Value Functions

In order to model the preferences of a decision maker, we may wish to consider a “strength of preference” notion that involves comparisons of preference differences between pairs of alternatives. To do so, we need more restrictive preference assumptions, including that of a weak order over preferences between exchanges of pairs of alternatives (Chapter 4, [17]). We use the term *measurable value function* for a value function that may be used to order the differences in the strength of preference between pairs of alternatives or, more simply, the “preference differences” between the alternatives.

Once again, we begin with a discussion of a preference model for a single attribute. Let X denote the set of all possible consequences in a decision situation, with $w, x, y, z, w', x', y' \in X$; define X^* as a nonempty subset of $X \times X$, and $\succsim^*$ as a binary relation on X^* . That is, X^* is a set of paired values for the original set of outcomes or consequences X , so if X is a set of automobiles, then X^* would be a pair of automobiles. We will be interested in how much difference we perceive in our strength of preference for one of these automobiles versus our strength of preference for the other one. We shall interpret $wx \succsim^* yz$ to mean that the strength of preference for w over x is greater than or equal to the strength of preference for y over z . The notation $wx \sim^* yz$ means both $wx \succsim^* yz$ and $yz \succsim^* wx$, and $wx \succ^* yz$ means not $yz \succsim^* wx$.

We emphasize again that we are comparing the strength of preference for one alternative over another from the same set of alternatives. One way to think about this comparison is to focus on the notion of having the opportunity to exchange x for w , or to exchange y for z . If the decision maker would prefer the former exchange to the latter one, then $wx \succsim^* yz$.

We use the axiom system for positive difference structures presented by Krantz *et al.* [17]. This set of axioms includes several technical assumptions that have no significant implications for behavior. However, a key axiom that does have an intuitive interpretation in terms of preferences is the following one: If $wx, xy, w'x', x'y' \in X^*$, $wx \succsim^* w'x'$, and $xy \succsim^* x'y'$,

then $wy \succsim^* w'y'$. That is, if the difference in the strength of preference between w and x exceeds the difference between w' and x' , and the difference in the strength of preference between x and y exceeds the difference between x' and y' , then the difference in the strength of preference between w and y must exceed the difference between w' and y' .

To provide some intuition for this axiom, suppose that a shopper is trying to choose a car based on its color; the cars are identical on all other attributes. He or she might feel, for example, that he or she would prefer to exchange a blue car for a black one versus the exchange of a white car for a silver one. And, he or she might prefer to exchange a red car for a blue one versus the exchange of a yellow car for a white one. Then, it seems logical that he or she would prefer to exchange a red car for a black one versus the exchange of a yellow car for a silver one.

The axioms of Krantz *et al.* [17] imply that there exists a real-valued function v on X such that, for all $w, x, y, z \in X$, if w is preferred to x and y to z , then $wx \succsim^* yz$ if and only if

$$v(w) - v(x) \geq v(y) - v(z) \quad (7)$$

Further, v is unique up to a positive linear transformation, so it is a *cardinal function* (i.e., v provides an *interval scale of measurement*). That is, if v' also satisfies (7), then there are real numbers $a > 0$ and b such that $v'(x) = av(x) + b$ for all $x \in X$ ([17], Theorem 4.1).

We define the binary preference relation $\succsim$ on X from the binary relation $\succsim^*$ on X^* in the natural way by requiring $wx \succsim^* yx$ if and only if $w \succsim y$ for all $w, x, y \in X$. Then, from (7), it is clear that $w \succsim y$ if and only if $v(w) \geq v(y)$. Thus, v is a value function on X and, by virtue of (7), it is a *measurable value function*.

The ideas of strength of preference and of measurable value functions are important concepts that are often used implicitly in the implementation of preference theories in practice. Further, the measurable value function can be assessed using questions for subjects that do not require choices among lotteries, which may be artificial distractions in cases where subjects are trying to choose among alternatives that do not require

the consideration of risk. Examples of methods for assessing measurable value functions would include direct rating of alternatives on a cardinal scale, or direct comparisons of preference differences. For a detailed discussion of these approaches, see Keller [17], Farquhar and Keller [18], von Winterfeldt and Edwards [7], and Kirkwood [16].

It is important to note that the measurable value function and the utility function of an individual assessed over the same attribute range may be different. This would mean that an individual's preferences among risky alternatives captured by $u(x)$ could be different from his or her preferences for certain outcomes captured by $v(x)$. Therefore, it would not be logically consistent to take the expected value of a preference function $v(x)$ that is assessed using questions that do not involve risk.

As an example of a situation where utility and value functions can be distinct for the same individual, consider asking an individual to specify the price he or she would be willing to pay for a coin flip that pays \$20 for heads and \$0 for tails. In our classroom experiences with students, there are always a few who specify a price of \$10—the expected value of the lottery—but the modal response is typically around \$5 or \$6, indicating that these students tend to be very risk averse and, therefore, that their utility functions would be concave. However, suppose that you ask these same students, “How much money would you have to receive to feel twice as satisfied as if you received \$10?” Most students will say “\$20” indicating that the value function for money in this range from \$0 to \$10 is linear, which implies that the marginal value of \$1 is \$1. In this case, the value and utility functions for the typical student would have different shapes.

We acknowledge that the students are giving quick reactions that may highlight their risk aversion in the question about the coin flip, and that some of them might agree that they should be willing to pay closer to the expected value for a coin flip with such small outcomes if this is pointed out to them. Nevertheless, it is also possible that some students would feel that their utility functions representing their risky preferences are

quite different from their value functions representing the marginal value of additional dollars.

As a practical matter, however, the difference between $v(x)$ and $u(x)$ may not be significant in a decision context [7]. The relationship between these two measures of preferences is also discussed in Dyer and Sarin [19].

Measurable Multiattribute Preference Functions for the Case of Certainty

Let $X^* = \{wx | w, x \in X\}$ be a nonempty subset of $X \times X$, and $\succsim^*$ denote a weak order on X^* . Once again, we may interpret $wx \succsim^* yz$ to mean that the preference difference between w and x is greater than the preference difference between y and z . In this case, however, we allow the outcomes defined for the preference functions to be vectors. That is, suppose that $X = X_1 \times X_2 \times \dots \times X_n$ where X_i represents the performance of an alternative on attribute i .

It seems reasonable to assume a relationship between $\succsim$ on X and $\succsim^*$ on X^* as follows. Suppose that the attributes $X_1, \dots, X_n$ are mutually preference independent. These two orders are *difference consistent* if, for all $w_i, x_i \in X_i$, $(w_i, \bar{w}_i) \succsim (x_i, \bar{w}_i)$ if and only if $(w_i, \bar{w}_i)(x_i^\circ, \bar{w}_i) \succsim^* (x_i, \bar{w}_i)(x_i^\circ, \bar{w}_i)$ for some $x_i^\circ \in X_i$ and some $\bar{w}_i \in \bar{X}_i$, and for any $i \in \{1, \dots, n\}$, and if $w \sim x$, then $wy \sim^* xy$ or $yw \sim^* yx$ or both for any $y \in X$. Loosely speaking, this means that if one multiattributed alternative is preferred to another, then the preference difference between that alternative and some common reference alternative $(x_i^\circ, \bar{w}_i)$ will be larger than the preference difference between the alternative that is not preferred and this reference alternative.

Weak Difference Independence

In the case of certainty, weak difference independence plays a role similar to the utility independence condition in multiattribute utility theory. Specifically, the subset of attributes X_I is weak difference independent of $\bar{X}_I$ if, given any $w_I, x_I, y_I, z_I \in X_I$ and some $\bar{w}_I \in \bar{X}_I$ such that the subject's judgments regarding strength of preferences between pairs of multiattributed alternatives

is as follows: $(w_I, \bar{w}_I)(x_I, \bar{w}_I) \succ^*(y_I, \bar{w}_I)(z_I, \bar{w}_I)$, then the decision maker will also consider $(w_I, \bar{x}_I)(x_I, \bar{x}_I) \succ^*(y_I, \bar{x}_I)(z_I, \bar{x}_I)$ for any $\bar{x}_I \in \bar{X}_I$. That is, the ordering of preference differences depends only on the values of the attributes X_I and not on the fixed values of $\bar{X}_I$. The attributes are mutually weak difference independent if all proper subsets of these attributes are weak difference independent of their complementary subsets.

A measurable multiattribute value function $v(x_1, x_2, \dots, x_n)$ on X can be of similar form as a utility function. For example, X may have the multiplicative form

$$1 + \lambda v(x_1, x_2, \dots, x_n) = \prod_{i=1}^n [1 + \lambda \lambda_i v(x_i)] \quad (8)$$

if and only if $X_1, \dots, X_n$ are mutually weak difference independent, where v_i is a single-attribute measurable value function over X_i scaled from 0 to 1, the λ_i are positive scaling constants, and λ is an additional scaling constant. If the scaling constant λ is determined to be 0 through the appropriate assessment procedure, then 8 reduces to the additive form

$$v(x) = \sum_{i=1}^n \lambda_i v_i(x_i)$$

where $\sum_{i=1}^n \lambda_i = 1$.

Difference Independence

Once again, we see that the additive form for measurable value functions is a special case of the multiplicative form, and this can be discovered through the assessment procedures. However, we may wish to identify the stronger preference conditions that do imply an additive measurable multiattribute preference function for the case of certainty. Mutual preference independence guarantees the existence of an additive preference function for the case of certainty that will provide an ordinal ranking of alternatives, but it may not capture the underlying strength of preference of the decision maker.

The required condition for additivity that also provides a measurable preference

function is called *difference independence*. The attribute X_i is difference independent of $\bar{X}_i$ if, for all $w_i, x_i \in X_i$ such that $(w_i, \bar{w}_i) \succ (x_i, \bar{w}_i)$ for some $\bar{w}_i \in \bar{X}_i$, $(w_i, \bar{w}_i)(x_i, \bar{w}_i) \sim^*(w_i, \bar{x}_i)(x_i, \bar{x}_i)$ for any $\bar{x}_i \in \bar{X}_i$. Intuitively, the preference difference between two multiattributed alternatives differing only on one attribute does not depend on the common values of the other attributes.

The attributes are mutually difference independent if all proper subsets of these attributes are difference independent of their complementary subsets. For the case of $n \geq 3$, mutual difference independence along with some additional structural and technical conditions² ensure that if $wx, yz \in X^*$, then $wx \succ^* yz$ if and only if

$$\begin{aligned} \sum_{i=1}^n \lambda_i v_i(w_i) - \sum_{i=1}^n \lambda_i v_i(x_i) &\geq \sum_{i=1}^n \lambda_i v_i(y_i) \\ &- \sum_{i=1}^n \lambda_i v_i(z_i) \end{aligned}$$

and $x \succ y$ if and only if

$$\sum_{i=1}^n \lambda_i v_i(x_i) \geq \sum_{i=1}^n \lambda_i v_i(y_i)$$

where v_i is a single-attribute measurable value function over X_i scaled from 0 to 1, and $\sum_{i=1}^n \lambda_i = 1$. Further, if $v_i', i = 1, \dots, n$ are n other functions with the same properties, then there exist constants $\alpha > 0, \beta_1, \dots, \beta_n$ such that $v_i' = \alpha v_i + \beta_i, i = 1, \dots, n$.

Verification of the independence conditions necessary to apply multiattribute value theory is discussed in detail by Keeney and Raiffa [5], von Winterfeldt and Edwards [7], and Kirkwood [6]. Assessing individual measureable value functions is discussed

²Specifically, we assume restricted solvability from below, an Archimedean property, at least three attributes are essential, and that the attributes are bounded from below. If $n = 2$, we assume that the two attributes are preferentially independent of one another and that the Thomsen condition is satisfied (see Krantz *et al.* [17]).

in Dyer and Sarin [20] and Salo and Hamalainen [21].

The necessary conditions for the additive and multiplicative measurable value functions and risky utility functions, notably mutual preference independence, are very similar and so it is natural to investigate the relationships among them. To illustrate an important result regarding the decision maker's preferences, consider the following statements:

1. $X_1, \dots, X_n$ are difference consistent and X_1 is difference independent of $\bar{X}_1$.
2. There exists a utility function u on X and preferences over lotteries on $X_1, \dots, X_n$ depend only on their marginal probability distributions and not on their joint probability distributions.

If statements 1 and 2 are both true, then $v(x_1, x_2, \dots, x_n) = u(x_1, x_2, \dots, x_n)$ and both are additive. Loosely speaking, the additive independence concepts for utility functions and measurable value functions imply that the values of the other attributes have no impact on either the shape of the preference function on each attribute or on the relative importance of each attribute. Therefore, the additive preference function can be assessed using either questions involving risk, or questions involving strength of preference and the results should be identical. Otherwise, it may be possible to transform a multiattribute value function into a multiattribute utility function and vice versa [20].

Finally, there are many examples of multiattribute preference models that are presented as alternatives to multiattribute utility or value theory. One of the most commonly utilized multiattribute preference approaches is the analytic hierarchy process (AHP). The AHP estimates ratios of importance and preference and integrates them into an additive model of preference under certainty. However, as typically implemented, the AHP does not require decision makers to consider the range of attribute performance when making these ratio judgments which may lead to arbitrary rankings of alternatives or to rank reversals when new alternatives are introduced [22].

However, the subjects can be asked to make ratio comparisons of preference *differences* rather than to make ratio judgments where there is no natural zero-point on a preference scale, and the results may provide a valid alternative for assessing a measurable multiattribute value function (e.g., see [21–24]).

DISCUSSION

In the theoretical development presented here, it is assumed that the vector of attributes $X = X_1, X_2, \dots, X_n$ is given. Whether the decision maker is operating in a setting of certainty or uncertainty, the identification of the correct set of attributes is difficult and a key precursor to a successful multiattribute decision analysis. Prescriptive decision analysis suggests identifying the fundamental objectives—what the decision maker really cares about—and then constructing a value hierarchy by decomposing these objectives until quantifiable attributes can be identified. Keeney's (1992) concept of value-focused thinking is one of the earliest attempts to formalize the process of identifying fundamental objectives that form the basis for the value hierarchy. [25]

In this article, we have presented an informal discussion of “multiattribute utility theory.” In fact, this discussion has emphasized that there is no *single* version of multiattribute utility theory that is relevant to *all* multicriteria decision analyses. Instead, the appropriate method should be driven by the decision context. Specifically, we focused on two distinct theories of multiattribute preference functions that may be used to represent a decision maker's preferences under conditions of risk or certainty, respectively.

Multiattribute utility theory is an elegant and useful model of preference suitable for applications involving risky choice. The seminal work of Keeney and Raiffa [5] has made this theory synonymous with multicriteria decision-making, and the measurable theories are often overlooked or ignored as a result. In fact, the latter approaches may provide more attractive and appropriate theories for many applications of multicriteria decision analysis.

INTRODUCTION TO POINT PROCESSES

FREDERIC PAIK SCHOENBERG
UCLA Department of Statistics,
Los Angeles, California

A point process is a random collection of points falling in some space. In most applications, each point represents the time and/or location of an event, such as a lightning strike or earthquake. When modeling purely temporal data, the space in which the points fall is simply a portion of the real line.

Figure 1 shows an example of origin times of Southern California earthquakes of magnitude at least 3.0 occurring in 2008, obtained from the Southern California Earthquake Data Center. Point process data arise in a wide variety of scientific applications, including epidemiology, ecology, forestry, mining, hydrology, astronomy, ecology, and meteorology.

FORMAL DEFINITIONS

There are several ways of characterizing a point process. The usual approach is to define a point process N as a random measure on a complete separable metric space S taking values in the nonnegative integers $\mathbf{Z}^+$ (or infinity). In this framework the measure $N(A)$ represents the number of points falling in the subset A of S . Attention is typically restricted to the case where N may only contain finitely many points on any bounded subset of S .

The random measure definition above is perhaps not the most intuitive means of characterizing a point process, and several alternatives exist. Consider the case of a temporal point process, for example, the times of events occurring between time 0 and time T . One may characterize N as an ordered list $\{\tau_1, \dots, \tau_n\}$ of event times. One may alternatively convey the equivalent information about N via the interevent times $\{u_1, \dots, u_n\}$,

where $u_i = \tau_i - \tau_{i-1}$, with the convention that $\tau_0 = 0$.

A temporal point process N may alternatively be described by a counting process $N(t)$, where for any time t between 0 and T , $N(t)$ is the number of points occurring at or before time t . The resulting process $N(t)$ must be nondecreasing and right-continuous, and take only nonnegative integer values. One could thus define a temporal point process as any nondecreasing, right-continuous $\mathbf{Z}^+$ -valued process. This sort of definition has been used by Jacod [1], Brémaud [2], Andersen *et al.* [3], and others.

The counting process definition of a point process lends itself naturally to discussions of martingales and distributional theory. On the other hand, the random measure formulation has the advantage of generalizing immediately to point processes in higher dimensions and in abstract spaces. For simplicity, the remainder of this article will deal only with purely temporal point processes, where the domain S is simply a portion of the real (time-)line.

A point process is called *simple* if with probability one, all its points τ_i occur at distinct times. A closely related concept is orderliness: a point process N is *orderly* if for any time t , $P\{N(t, t + \Delta t) > 1\}/\Delta t \rightarrow 0$ as $\Delta t \rightarrow 0$.

The points of a point process are typically indistinguishable other than by their times and/or locations. When there is other important information to be stored along with each point, such as a list of times of wildfire origin times along with their corresponding burn areas, or the earthquake times and magnitudes shown in Fig. 1, the result may be viewed as a *marked* point process.

The relationship between time series and point processes is worth noting. Many data sets that are traditionally viewed as realizations of (marked) point processes could, in principle, also be regarded as time series, and vice versa. For instance, a sequence of earthquake origin times is typically viewed as a temporal point process; however, one

Figure 1. Times and magnitudes of Southern California earthquakes occurring in 2008, with magnitude at least 3.0, compiled by the Southern California Earthquake Data Center.

could also store such a sequence as a time series consisting of zeros and ones, with the ones corresponding to earthquakes. The main difference is that, for a point process, the points can occur at any time in a continuum, whereas the time intervals are discretized in the time series case.

POINT PROCESS MODELS

The most important point process model is the *Poisson process*, which is a simple point process N such that the number of points in any set follows a Poisson distribution and the numbers of points in disjoint sets are independent. That is, N is a Poisson process if $N(A_1), \dots, N(A_k)$ are independent Poisson random variables, for any disjoint, measurable subsets $A_1, \dots, A_k$ of S .

The behavior of a simple temporal point process N is typically modeled by specifying its *conditional intensity*, $\lambda(t)$, which represents the infinitesimal rate at which events are expected to occur around a particular time t , conditional on the prior history of the point process prior to time t . Formally, the conditional intensity associated with a temporal point process N may be defined via the limiting conditional expectation

$$\lambda(t) = \lim_{\Delta t \rightarrow 0} E\{N[t, t + \Delta t] | H_t\} / \Delta t,$$

provided this limit exists, where H_t is the history of the point process N over all times strictly prior to time t . Some authors instead define λ as the conditional probability

$$\lambda(t) = \lim_{\Delta t \rightarrow 0} P\{N[t, t + \Delta t] > 0 | H_t\} / \Delta t,$$

since the two definitions are equivalent for orderly point processes. As all finite-dimensional distributions of N are uniquely determined by the conditional intensity [4,5], in modeling N , it suffices to prescribe a model for λ .

For a temporal point process originating at time 0, one may define the *compensator* $A(t)$ as the integral of the conditional intensity from time 0 to time t . The compensator may equivalently be defined as the unique nonnegative, nondecreasing predictable process $A(t)$ such that $N[0, t] - A(t)$ is a martingale [1,2].

λ may be estimated nonparametrically [6–9], or via a parametric model. In general, $\lambda(t)$ depends not only on t but also on the times τ_i of preceding events. When N is a Poisson process, however, λ is deterministic; that is, $\lambda(t)$ depends only on t .

A stationary Poisson process has constant conditional rate: $\lambda(t) = \alpha$, for all t . This model posits that the risk of an event is the same at all times, regardless of how frequently such events have occurred previously. For a nonstationary Poisson process, $\lambda(t)$ is some function of t . A generalization is the Cox process, or doubly-stochastic Poisson process, which is a Poisson process whose intensity function is randomly generated.

Another important elementary type of temporal point process is the *renewal process*. A renewal process is a simple point process such that the interevent times $\{u_1, \dots, u_n\}$ are independent (typically i.i.d.) random variables. In the i.i.d. case, the density function governing each interevent time is called the *renewal density*. Note that the renewal density f is ordinarily taken to be a density

on the half-line, that is, $f(t) = 0$ for $t < 0$. Renewal models embody the notion that the hazard of an event occurring at a particular time depends only on the time since the most recent event. In wildfire hazard analysis, for example, such a model is consistent with the theory of fuel loading followed by complete fuel depletion in the event of a fire.

A point process N may be called *self-exciting* if $\text{cov}\{N(s, t), N(t, u)\} > 0$ for $s < t < u$. N is *self-correcting* if instead this covariance is negative. Thus the occurrence of points in a self-exciting point process causes other points to be more likely to occur, whereas in a self-correcting process, the points have an inhibitory effect. By definition, a Poisson process is neither self-exciting nor self-correcting.

Self-exciting point process models are often used to model events that are temporally clustered. A commonly used example is the *Hawkes process*, where the conditional intensity is given by

$$\lambda(t) = \mu(t) + \sum_{i: \tau_i < t} \nu(t - \tau_i),$$

where $\mu(t)$ represents the deterministic background rate and the function ν governs the clustering density. An example where $\mu(t)$ is constant was offered by Hawkes and Adamopoulos [10]. Hawkes models are commonly used in seismology, where they are sometimes called *epidemic-type aftershock sequence* (ETAS) models, encompassing the notion that earthquakes can have aftershocks, and those aftershocks can have aftershocks, and so on. A form of the clustering density ν that is commonly used in modeling earthquake aftershocks is the Omori–Utsu law [11]

$$\nu(t) = \kappa(t + c)^{-p},$$

which corresponds to power-law decay in the clustering behavior over time.

Alternative versions of clustered point processes are formed by generating a sequence of parents and then placing clusters of points (offspring) around each parent. For the Neyman–Scott process, for instance, the offspring points are independently and identically distributed around the parents, and

for the Bartlett–Lewis process the offspring points are each generated via a renewal process originating at the corresponding parent.

Self-correcting models are used in ecology, forestry, and other fields to model occurrences that are well-dispersed. Such models may be useful in describing births of species, for example, or in seismology for modeling earthquake catalogs after aftershocks have been removed [12]. An important example is the Markovian point process model (so called because the conditional rate obeys the Markov property), where

$$\lambda(t) = g\{t, N[0, t)\}.$$

For example, the function g may be selected so that λ takes the form

$$\lambda(t) = \exp\{\alpha + \beta(t - \rho N[0, t))\},$$

where α , β , and ρ are constants [13–15]. The parameters α and β govern the background rate and trend in the occurrences, while the product $\beta\rho$ represents the decrease in conditional rate of future events caused by each event, which may be due to diminished fuel load in the case of wildfire modeling, for instance, or the release of strain energy in the seismological case.

TRANSFORMATIONS

Some important operations on point processes include superposition, thinning, and rescaling. Graphically, these operations correspond, respectively, to overlaying points of one process onto those of another point process, deleting certain points, and stretching out the time axis.

The Poisson process frequently arises as a limiting process resulting from transformations of point processes. For example, under quite general conditions, when k independent copies of a temporal point process are superposed and the time axis is rescaled by a factor of k , the resulting process converges to a Poisson process (for details see Refs 16 and 17). Similar results can be obtained for randomly thinned point processes [18] or rescaled point processes [19].

ESTIMATION AND SIMULATION

The parameter vector θ for a point process model with conditional intensity $\lambda(\theta)$ is typically estimated by maximizing the log-likelihood function

$$L(\theta) = \sum_i \log \lambda(\tau_i; \theta) - \int_S \lambda(t) dt.$$

The consistency, asymptotic normality, and efficiency of maximum likelihood estimators have been established under standard conditions [20,21], and standard errors may be obtained via the Hessian of the log-likelihood [22–24].

Alternatively, simulations may be useful for obtaining approximate standard errors and for other types of inference. An effective simulation method for point processes based on random thinning was devised in Refs 25 and 26. The procedure, which works for point processes whose conditional rate λ is bounded (or locally bounded) above by some constant b , involves simulating a (locally) stationary Poisson process with intensity b and thinning it, keeping each point τ_i with probability $\lambda(\tau_i)/b$.

MODEL EVALUATION

The fit of a parametric point process model is often assessed using a likelihood score such as the Akaike Information Criterion (AIC), which is defined as $2p - 2L(\theta)$, where p is the number of fitted parameters. The AIC rewards a model for higher likelihood and penalizes a model for overfitting; lower AIC indicates better fit.

Residual analysis methods for point processes often involve comparing the number of points observed with the integrated conditional intensity within specified portions of S . Methods for normalizing and inspecting such residuals are described in Ref. 27.

Another useful technique for evaluating point process models is via rescaling. The method essentially involves rescaling the time axis of the observed point process N at time t by a factor of $\lambda(t)$. More specifically, if the points are observed from time 0 to time t , then each point τ_i is moved to the new time

$A(\tau_i)$, where A is the compensator. The resulting process M is a stationary Poisson process with unit rate, provided the original point process is simple [19]. Similarly, one may inspect residuals obtained by randomly thinning the process, that is, keeping each point τ_i independently with probability inversely proportional to $\lambda(\tau_i)$. As with rescaled residuals, the resulting thinned residuals will be distributed according to a stationary Poisson process [28]. In practice, one may use the estimated intensity or compensator in place of the true intensity or compensator and inspect the rescaled or thinned process for uniformity. Several tests exist for this purpose, with different uses depending on the alternative hypotheses [3,29–33]. Some of the most useful are tests based on second- and higher-order properties [34–37]. There are also more general second-order tests for point processes that do not rely on a stationary Poisson null hypothesis [38–40].

For further reading on point processes, see Refs 5 and 17.

INTRODUCTION TO POLYNOMIAL TIME ALGORITHMS FOR LP

TAMÁS TERLAKY

Department of Industrial and Systems
Engineering, Lehigh University,
Bethlehem, Pennsylvania

INTRODUCTION

Since the path-breaking paper of Khachiyan [1], a tremendous amount of research was devoted to the study of polynomial time algorithms for linear programming (LP)¹ Khachiyan [1] has developed the foundations of the theory underlying all polynomial time algorithms for LP. He presented the first *condition number*, the input bit-length of an LP problem given by integer (or rational) data. In the second section, we present some frequently used condition numbers, and then in the third section, a simple variant of the ellipsoid method is presented.

Over the last quarter century, interior point methods (IPMs) dominate the literature of polynomial time algorithms for LP. In 1984, Karmarkar [3] presented the first polynomial time IPM. By now, path-following IPMs are among the most efficient methods for solving linear, and also wide classes of general convex optimization problems. Hundreds of polynomial time IPM variants were developed for LP. Interior point software implementations have challenged simplex method implementations, and frequently surpassed their performance [4–6]. All aspects of linear optimization (LO) had to be revisited. Not only the research on algorithms exploded, but so did the research on duality theory [2,7]. The book of Roos *et al.* [2] presents a thorough treatment of the IPM-based theory—duality, initialization, complexity, sensitivity analysis,

implementation strategies—and large classes of IPMs for LP.

This article is structured as follows. The section LP Duality and Condition Numbers summarizes key duality results of LP, and presents condition numbers that indicate the difficulty of the problem. The ellipsoid method is presented in the section The Ellipsoid Method, while in the section IPMs for LP, we give a brief introduction to IPMs for LP. In the fifth section, we review some extensions of polynomial time algorithms (mainly IPMs) to convex conic and nonlinear optimization.

Notation

In this article, $\mathbb{R}_+^n$ denotes the set of nonnegative vectors in $\mathbb{R}^n$. Throughout, we use $\|\cdot\|_p$ ($p \in \{1, 2, \infty\}$) to denote the p -norm on $\mathbb{R}^n$, with $\|\cdot\|$ denoting the Euclidean norm $\|\cdot\|_2$. The identity matrix is denoted by I , e denotes the vector that has all of its components equal to one. Given an n -dimensional vector x , the matrix X denotes the $n \times n$ diagonal matrix whose diagonal entries are the coordinates x_j of x . If $x, s \in \mathbb{R}^n$ then $x^T s$ denotes the dot product of the two vectors, while xs denotes the coordinatewise product of the vectors x and s .

LP DUALITY AND CONDITION NUMBERS

The Linear Optimization Problem, Duality

We consider the general LP problem (P) and its dual (D) in canonical form:

$$\min \{c^T x : Ax \geq b, x \geq 0\}, \quad (P)$$

$$\max \{b^T y : A^T y \leq c, y \geq 0\}, \quad (D)$$

where A is an $m \times \ell$ matrix, $b, y \in \mathbb{R}^m$ and $c, x \in \mathbb{R}^\ell$. It is well known that by using only elementary transformations, any given LP problem can easily be transformed into a “minimal” canonical form. These transformations [2] can be summarized as follows:

¹Linear programming is frequently referred to as *linear optimization (LO)* [2].

- introduce slack variables in order to get equations (if a variable has both lower and upper bounds, then one of these bounds is transformed to an inequality constraint);
- shift the variables with lower or upper bound so that the respective bound becomes 0 and, if needed replace the variable by its negative;
- eliminate free variables;
- use Gaussian elimination to transform the problem into a form, where all equations have a singleton column (i.e., choose a basis and multiply the equations by the basis inverse), while dependent constraints are eliminated.

The weak duality theorem sets the stage for establishing the fundamental duality relationship between the primal problem (P) and its dual (D).

Theorem 1 [Weak duality for linear optimization]. *Let us assume that $x \in \mathbb{R}^\ell$ and $y \in \mathbb{R}^m$ are feasible solutions for the primal problem (P) and dual problem (D), respectively. Then one has*

$$c^T x \geq b^T y,$$

where equality holds if and only if²

- (i) $x_i(c - A^T y)_i = 0$ for all $i = 1, \dots, \ell$ and
- (ii) $y_j(Ax - b)_j = 0$ for all $j = 1, \dots, m$.

The Weak Duality Theorem implies the following sufficient optimality condition.

Corollary 1. *Let a primal and dual feasible solution $x \in \mathbb{R}^\ell$ and $y \in \mathbb{R}^m$ with $c^T x = b^T y$ be given. Then x is an optimal solution of*

²These conditions are in general referred to as the *complementarity conditions*. Using the coordinatewise notation we may write $x(c - A^T y) = 0$ and $y(Ax - b) = 0$, or by introducing the slack variables $z = Ax - b$ and $s = c - A^T y$ we have $xs = 0$ and $yz = 0$. By the weak duality theorem complementarity and feasibility imply optimality.

the primal problem (P) and y is an optimal solution of the dual problem (D).

Although the Weak Duality Theorem provides a sufficient condition to check optimality of a feasible solution pair, it does not prove that for every feasible primal-dual LP problem pair, an optimal pair of solutions with zero duality gap exists. This is the so-called Strong Duality Theorem that can be proved for example, by using only simple calculus and fundamental concepts of IPMs [2].

As, optimistically, we are looking for optimal solutions with zero duality gap, we utilize the results of the Weak Duality Theorem (Theorem 1); thus, we need to find a solution of the inequality system formed by the primal and the dual feasibility constraints and by requiring that the dual objective is at least as large as the primal one (reversed weak duality inequality). For this system, we already know that any solution of this system gives both a primal and a dual feasible solution with equal objective values; thus, by Corollary 1, these solutions are optimal.

$$\begin{aligned} -Ax &\leq -b, & x &\geq 0, \\ A^T y &\leq c, & y &\geq 0, \\ -b^T y + c^T x &\leq 0. \end{aligned}$$

The Strong Duality Theorem of LP [2,8] says that solving this inequality system is equivalent to solving the primal and dual LP problems (P) and (D). By introducing the notation

$$\tilde{A}^T = \begin{pmatrix} 0 & -A \\ A^T & 0 \\ -b^T + c^T \end{pmatrix}, \quad \tilde{c} = \begin{pmatrix} -b \\ c \\ 0 \end{pmatrix},$$

$$\tilde{y} = \begin{pmatrix} y \\ x \end{pmatrix} \geq 0,$$

solving the LP problem is equivalent to solving the feasibility problem

$$\tilde{A}^T \tilde{y} \leq \tilde{c}, \quad \tilde{y} \geq 0. \quad (FP)$$

Optimal Partition

Roos *et al.* [2] and Goldman and Tucker [9] proved that whenever optimal solutions exist, the primal-dual LP problem pair (P) and (D)

always has strictly complementary optimal solutions (x, z) and (s, y) , where slack variables are defined as $z = Ax - b$, and $s = c - A^T y$. Strictly complementary optimal solutions are feasible for the primal and dual problems, respectively and satisfy

$$xs = 0, \quad x + s > 0, \quad zy = 0, \quad y + z > 0.$$

The existence of strictly complementary optimal solutions allow us to introduce the *optimal partition* of the index sets:

$$\begin{aligned} \mathbf{B}_x &= \{j : x_j > 0\}, & \mathbf{B}_z &= \{i : z_i > 0\} \\ \mathbf{N}_x &= \{j : s_j > 0\}, & \mathbf{N}_z &= \{i : y_i > 0\}. \end{aligned}$$

One easily see that

$$\begin{aligned} \mathbf{B}_x \cap \mathbf{N}_x &= \emptyset, \quad \mathbf{B}_x \cup \mathbf{N}_x = \{1, \dots, \ell\}, \quad \text{and} \\ \mathbf{B}_z \cap \mathbf{N}_z &= \emptyset, \quad \mathbf{B}_z \cup \mathbf{N}_z = \{1, \dots, m\}. \end{aligned}$$

A Condition Number

We first introduce the following two numbers:

$$\begin{aligned} \sigma^P &:= \min \left\{ \min_{j \in \mathbf{B}_x} \max_{x \in \mathcal{P}^*} \{x_j\}, \min_{i \in \mathbf{B}_z} \max_{z \in \mathcal{P}^*} \{z_i\} \right\}, \\ \sigma^D &:= \min \left\{ \min_{j \in \mathbf{N}_x} \max_{s \in \mathcal{D}^*} \{s_j\}, \min_{i \in \mathbf{N}_z} \max_{y \in \mathcal{D}^*} \{y_i(x)\} \right\}, \end{aligned}$$

where $\mathcal{P}^*$ and $\mathcal{D}^*$ denote the set of primal and dual optimal solutions, respectively. By convention we take $\sigma^P = \infty$ if both $\mathbf{B}_x$ and $\mathbf{B}_z$ are empty, and analogously $\sigma^D = \infty$ if both $\mathbf{N}_x$ and $\mathbf{N}_z$ are empty. Owing to the definition of strictly complementary solutions, both σ^P and σ^D are positive. As a consequence, the number

$$\sigma := \min \left\{ \sigma^P, \sigma^D \right\}$$

is positive as well. This number plays a crucial role in the further analysis and is called the *condition number* of LP problem (P) .³

³This condition number seems to be a natural quantity for measuring the degree of hardness of (P) and (D) . The smaller the number the more difficult it is to find a strictly complementary solution,

For the calculation of σ we need to know the maximal value of each coordinate of the vector (x, z, s, y) when this vector runs through all possible optimal solutions of (P) and (D) , and σ is the smallest of all of those maximal values. The following lemma enables us to give an estimate for σ_{SP} .

Lemma 1. *Let A be an integer $m \times n$ matrix with columns A_j and $b \in \mathbb{Z}^m$ so that the set*

$$\mathcal{F} := \{x : Ax = b, x \geq 0\}$$

is bounded and contains a positive vector. Then for each j , with $1 \leq j \leq n$,

$$\max_x \{x_j : x \in \mathcal{F}\} \geq \frac{1}{\prod_{j=1}^n \|A_j\|}.$$

Proof. Observe that each column A_j of A must be nonzero, due to the boundedness of $\mathcal{F}$. Fixing the index j , let $x \in \mathcal{F}$ be such that x_j is maximal. Note that such an x exists since $\mathcal{F}$ is bounded. Moreover, since $\mathcal{F}$ contains a positive vector, we must have $x_j > 0$. Let J be the support of x :

$$J = \{j : x_j > 0\}.$$

We may assume that the columns of the submatrix A_J are linearly independent. Let A_{KJ} be any nonsingular submatrix of A_J . Here K denotes a suitable subset of the row indices. Then we have

$$A_{KJ} x_J = b_K,$$

since the coordinates x_j of x with $j \notin J$ are zero. By using Cramer's rule⁴ we have

$$x_j = \frac{\det A'_{KJ}}{\det A_{KJ}}, \quad (1)$$

and the more difficult it is to differentiate a nonzero coordinate of a solution from a zero coordinate. In a more general context, this condition number was introduced by Ye [10]; see also Ye and Pardalos [11]. For a discussion of other condition numbers and their relation to the size of a problem we refer the reader to Vavasis and Ye [12].

⁴The idea of using Cramer's rule in this way was applied first by Khachiyan [1].

where A'_{KJ} denotes the matrix arising from A_{KJ} by replacing the j th column by b_K . We know that $x_j > 0$, consequently $|\det A'_{KJ}| > 0$. Since all entries of A'_{KJ} are integral, the absolute value of its determinant is at least 1, implying

$$x_j \geq \frac{1}{|\det A_{KJ}|}.$$

Owing to the Hadamard [2,13] inequality, we have that $|\det A_{KJ}|$ is bounded above by the product of the norms of its columns.⁵ We have

$$x_i \geq \frac{1}{\prod_{j \in J} \|A_{Kj}\|} \geq \frac{1}{\prod_{j \in J} \|A_j\|} \geq \frac{1}{\prod_{j=1}^n \|A_j\|}.$$

The second inequality is obvious and the last inequality follows since A has no zero columns and hence the norm of each column of A is at least 1. This proves the lemma.

Theorem 2. *Let assume that all problem data A, b, c are integers. Let $\tilde{A}_j$ denote the j th column of $\tilde{A}$. Then the condition number σ of (P) satisfies*

$$\sigma \geq \frac{1}{\prod_{j=1}^{m+\ell} \|\tilde{A}_j\|}.$$

One can give an upper bound for the coordinates of the basic solutions of problem (P) . Analogous to Lemma 1, using Cramer's rule and Hadamard's inequality one can derive the following bound.

Lemma 2. *Let A^B be an $m \times m$ nonsingular matrix with columns A_j^B and b a vector of dimension m such that the unique solution x^B of $A^B x^B = b$ is nonnegative. Let all the entries in A^B and b be integral. Then for each j one has*

$$x_j \leq \|b\| \prod_{j=1}^m \|A_j^B\|.$$

⁵The idea of using Hadamard's inequality for deriving bounds on the coordinates of x_j from Equation (1) was applied earlier by Kladfazy and Terlaky [13] in a similar context.

This provides a uniform upper bound for all the coordinates of the primal and dual basis solutions.

Theorem 3. *Let us assume that all problem data A, b, c are integers. Then, all the coordinates of the basis solutions of problems (P) and (D) are bounded by*

$$\bar{\sigma} := \|\tilde{c}\| \prod_{j=1}^{m+\ell} \|\tilde{A}_j\|.$$

Input Length L

Another characteristic number, analogous to the condition number σ , that also allows to give bounds on the size of the coordinates of basis solutions. Assume that all problem data A, b , and c are integers. Then the binary input length of problem (P) and (D) are given by

$$\begin{aligned} L = & \sum_{i=1}^m \sum_{j=1}^{\ell} \lceil \log_2 (|A_{ij}| + 1) \rceil \\ & + \sum_{i=1}^m \lceil \log_2 (|b_i| + 1) \rceil \\ & + \sum_{j=1}^{\ell} \lceil \log_2 (|c_j| + 1) \rceil \\ & + m\ell + m + \ell + 1. \end{aligned}$$

It is known [2,14] that $\sigma \geq 2^{-L}$, and that 2^L is an upper bound for all the coordinates of the basic solutions; thus, 2^{-L} can be considered as a condition number for LP problems (P) and (D) .

Polynomial Complexity

An algorithm for solving LP problems (P) and (D) is called a *polynomial time* algorithm, if the following hold:

- The number of iterations is bounded by a polynomial of the problem dimension $n \geq \max\{m, \ell\}$ and the logarithm of the condition number. *Note:* The reader may find in the literature polynomial iteration bounds expressed for example, as $\mathcal{O}(n^\gamma \log(\frac{1}{\sigma}))$ or $\mathcal{O}(n^\gamma L)$, where

usual values of γ are 0.5, 1, or 2. For algorithms that produce ϵ precise solutions, the iteration bound needs to depend only logarithmically on the precision, that is, the iteration bound may be $\mathcal{O}(n^\gamma \log \frac{n}{\epsilon})$.

- The number of arithmetic operations for each iterations is bounded by a polynomial of the dimension n . *Note:* Usually the number of arithmetic operations per iterations is in the range of $\mathcal{O}(n^2) - \mathcal{O}(n^3)$.
- If the algorithm does not produce an exact solution, then from a solution sufficiently close to optimality, a polynomial time rounding procedure allows to identify an exact optimal solution.

In the sequel we shortly discuss a variant of Khachiyan's polynomial time *ellipsoid method*, and a simple variant of *central path-following IPMs*.

THE ELLIPSOID METHOD

The presented variant is not the sharpest version of the ellipsoid method. Our aim is to present the main ideas, and present a simple, complete version. Proofs and details of this variant can be found in Klafszky and Terlaky [13]; see also Schrijver [14].

The next lemma shows, that if system (FP) has a solution, that is, LP problems (P) and (D) have optimal solutions, then by Theorem 3 (FP) has a solution in the “ $\bar{\sigma}$ cube,” that is, the infinity norm of the solution vector is less than or equal to $\bar{\sigma}$.

Lemma 3.

1. If $\tilde{A}^T \tilde{y} \leq \tilde{c}$ is consistent, then $\tilde{A}^T \tilde{y} \leq \tilde{c}$; $|\tilde{y}_i| \leq \bar{\sigma}$ for all index i is consistent. (Any basic solution has this property.)
2. If $\tilde{A}\tilde{x} = 0$, $\tilde{c}^T \tilde{x} = -1$, $\tilde{x} \geq 0$ is consistent, then $\tilde{A}\tilde{x} = 0$, $\tilde{c}^T \tilde{x} = -1$, $\tilde{x} \geq 0$, $\tilde{x}_j \leq \bar{\sigma}$ for all j is consistent. (Any basic solution has this property.)

This result and the Farkas Lemma [2,8] allows us to prove the following theorem.

Theorem 4. *Inequality system $\tilde{A}^T \tilde{y} \leq \tilde{c}$ is solvable if and only if the inequality system*

$$\begin{aligned} \tilde{A}^T \tilde{y} &\leq \tilde{c} + \frac{1}{m\ell\bar{\sigma}}e \\ |\tilde{y}_i| &\leq \bar{\sigma} + \frac{1}{m\ell\bar{\sigma}}, \quad \text{for all } i \end{aligned}$$

is solvable.

Corollary 2. *If the inequality system*

$$\begin{aligned} \tilde{A}^T \tilde{y} &\leq \tilde{c} + \frac{1}{m\ell\bar{\sigma}}e \\ |\tilde{y}_i| &\leq \bar{\sigma} + \frac{1}{m^2\ell\bar{\sigma}^2}, \quad \text{for all } i \end{aligned}$$

is solvable, then the set of solutions contains a cube with edge length $\frac{1}{m^2\ell\bar{\sigma}^2}$.

These results provide a polyhedron that is empty if and only if the original polyhedron is empty, and if not empty the new polyhedron contains a “small” cube, which guarantees that its volume is strictly positive.

The ellipsoid algorithm of the section titled “The Ellipsoid Algorithm and its Complexity”, and the procedure of the section titled “Find an Exact Solution” applied to the optimality conditions, represented by the matrix $\tilde{A}$ and vector $\tilde{c}$, yield a polynomial time algorithm that identifies an optimal solution of the LP problem, if it exists. For simplicity of notation, instead of $\tilde{A}^T \tilde{y} \leq \tilde{c}$ the notation $A^T y \leq c$ will be used in the next sections.

Ellipsoids

Ellipsoids and an ellipsoid transformation are examined in this section. It will be shown that the transformed ellipsoid contains a suitable half ellipsoid of the original ellipsoid and its volume is less than the volume of the original ellipsoid.

Definition 1. Let $P : m \times m$ be a positive definite matrix, and $z \in R^m$. Then the ellipsoid centered at z is given by

$$E = \text{ell}(z, P) = \left\{ x \in R^m \mid (x - z)^T P^{-1} (x - z) \right\}.$$

It is well known, that the set $\{x|a^T(x-z) \leq 0\}$ is the half-space, whose boundary contains point z and the normal vector of this half-space is vector a . A half-space through the center of an ellipsoid intersected by the ellipsoid provides a half ellipsoid.

Let an ellipsoid $E = \text{ell}(z, P)$ and a vector $a \in R^m$ be given. Let $E' = \text{ell}(z', P')$ be given as follows:

$$\begin{aligned} z' &= z - \frac{1}{m+1} \frac{Pa}{\sqrt{a^T P a}} \\ P' &= \frac{m^2}{m^2-1} \left(P - \frac{2}{m+1} \frac{Paa^T P}{a^T P a} \right). \end{aligned} \quad (2)$$

Now we will verify that E' is really an ellipsoid and it contains the half ellipsoid $E \cap$

$\{x|a^T(x-z) \leq 0\}$, and its volume is smaller than that of E .

Lemma 4. *For matrix P' and ellipsoid E' the following hold:*

- Matrix P' is positive definite.
- Ellipsoid E' contains the half ellipsoid $E \cap \{x|a^T(x-z) \leq 0\}$.
- $\frac{\text{vol}(E')}{\text{vol}(E)} < \exp\left(\frac{-1}{2(m+1)}\right)$.

The Ellipsoid Algorithm and its Complexity

The following ellipsoid method decides if the linear inequality system $A^T y \leq c$ is consistent or not.

Algorithm

Initialization: Let a matrix $A : m \times \ell$ and a vector $c \in R^\ell$ be given. Let us compute $\bar{\sigma}$ and let $E_0 = \text{ell}(z^0, P_0) = \text{ell}(0, 2\bar{\sigma}E)$ be the sphere with radius $2\bar{\sigma}$, be the initial ellipsoid.

Termination:

- If z^k satisfies $A^T z^k \leq c + \frac{1}{m\ell\bar{\sigma}}e$, then STOP, inequality system $A^T y \leq c$ is consistent.
- If $k = K > 2m(m+1)\log(4m^2\ell\bar{\sigma}^3)$, then STOP, the inequality system is inconsistent.

General step:

- If z^k does not satisfies $A^T z^k \leq c + \frac{1}{m\ell\bar{\sigma}}e$, then there is an index j for which

$$a_j^T z^k \leq c_j + \frac{1}{m\ell\bar{\sigma}}.$$

Let $a := a_j$, and according to formulas (2), let $z^{k+1} = z'$, $P_{k+1} = P'$, and $k = k+1$.

By Corollary 2 we know that inequality system $A^T y \leq c$ is consistent if and only if $A^T y \leq c + \frac{1}{m\ell\bar{\sigma}}e$ is consistent. So, we have to show that in case of $k=K$ the inequality system is indeed inconsistent.

Theorem 5. *If the above algorithm takes more than $2m(m+1)\log(4\bar{\sigma}^3 m^2 \ell)$ steps, then inequality system $A^T y \leq c$ is inconsistent.*

Proof. By Corollary 2 it is enough to show that inequality system $A^T y \leq c + \frac{1}{m\ell\bar{\sigma}}e$, $|y_i| \leq \bar{\sigma} + \frac{1}{m^2\ell\bar{\sigma}^2}$, for all i is inconsistent in this case. Corollary 2 says that its solution set, if it is

not empty, contains a cube with edge length $\frac{1}{m^2\ell\bar{\sigma}^2}$. The volume of this cube is $\left(\frac{1}{m^2\ell\bar{\sigma}^2}\right)^m$.

Lemma 4 implies that this cube is contained in all of the ellipsoids generated by the algorithms, and the volume of the actual ellipsoid after K steps can be estimated by Lemma 4 as follows:

$$\begin{aligned} \text{vol}(E_K) &< \exp\left(\frac{-K}{2(m+1)}\right) \text{vol}(E_0) \\ &< \exp\left(\frac{-K}{2(m+1)}\right) (4\bar{\sigma})^m. \end{aligned}$$

If this value is less than $\left(\frac{1}{m^2\ell\bar{\sigma}^2}\right)^m$, that is the volume of the ellipsoid is less than the

volume of the contained cube, then we have a contradiction, that is the inequality system is inconsistent,

$$\exp\left(\frac{-K}{2(m+1)}\right)(4\bar{\sigma})^m < \left(\frac{1}{m^2\ell\bar{\sigma}^2}\right)^m,$$

which holds if

$$K > 2m(m+1)\log(4m^2\ell\bar{\sigma}^3).$$

The proof is complete.

Since the number of steps of the algorithm can be bounded by a polynomial, and the computational cost per iteration is quadratic in the matrix dimension, the ellipsoid algorithm is a *polynomial time algorithm*. This way a polynomial time algorithm is constructed, which decides whether inequality system $A^T y \leq c$ is consistent or not. Unfortunately our algorithm gives a solution only for inequality system $A^T y \leq c + \frac{1}{m\ell\bar{\sigma}}e$, and the solution of this system is not necessarily a solution for system $A^T y \leq c$. Thus, we need

Algorithm

Step 0. Decide if the inequality system

$$a_1^T y \leq c_1, \dots, a_\ell^T y \leq c_\ell$$

is consistent or not. If it is inconsistent STOP.

Step 1. If it is consistent then decide if the inequality system

$$a_1^T y = c_1, \quad a_2^T y \leq c_2, \dots, a_\ell^T y \leq c_\ell$$

is consistent. If it is inconsistent, then it is enough to solve inequality system $a_2^T y \leq c_2, \dots, a_\ell^T y \leq c_\ell$, since in this case for all solutions of this system $a_1^T y < c_1$ holds. Let $\ell := \ell - 1$ and return to the previous step.

Step 2. If it is consistent then decide if the inequality system

$$a_1^T y = c_1, \quad a_2^T y = c_2, \quad a_3^T y \leq c_3, \dots, a_\ell^T y \leq c_\ell$$

is consistent.

$\vdots$

Step k. If it is consistent then decide if the inequality system

$$a_1^T y = c_1, \dots, a_k^T y = c_k, \quad a_{k+1}^T y \leq c_{k+1}, \dots, a_\ell^T y \leq c_\ell$$

to construct a polynomial time procedure for generating a solution of the original inequality system. This procedure subsequently calls the algorithm of this section.

Find an Exact Solution

Using Gaussian elimination and a polynomial time algorithm, which decides whether an inequality system is consistent or not, a solution of inequality system $A^T y \leq c$ can be found in polynomial time.

Theorem 6. *If we have an algorithm (e.g., ellipsoid method), which decides the consistency of a linear inequality system, then a solution can be found in polynomial time.*

Proof. The proof is constructive. By calling the algorithm at most ℓ times, and solving an equation system by Gaussian elimination at most ℓ times, a solution can be obtained.

is consistent. If it is inconsistent, then it is enough to solve inequality system $a_1^T y = c_1, \dots, a_{k-1}^T y = c_{k-1}$, $a_{k+1}^T y \leq c_{k+1}, \dots, a_\ell^T y \leq c_\ell$, since for all solutions of this system $a_k^T y < c_k$ holds. Let $\ell := \ell - 1$ and return to the previous step.

Step $k + 1$. If it is consistent then decide if the inequality system

$$a_1^T y = c_1, \dots, a_k^T y = c_k, a_{k+1}^T y = c_{k+1}, a_{k+2}^T y \leq c_{k+2}, \dots, a_\ell^T y \leq c_\ell$$

is consistent. ...

This algorithm finds a solution in polynomial time for inequality system $A^T y \leq c$, since in the last step an equation system is to be solved, which can be done by Gaussian elimination.

IPMs FOR LP

After decades of intensive research, deep understanding of IPMs has been developed. Easy to understand, simple variants of polynomial IPMs, as well as computationally highly efficient variants are published. The self-dual embedding model [2,7,15] provides an elegant, and powerful solution for the initialization problem of IPMs. As in case of the ellipsoid algorithm, we also demonstrate that IPMs not only converge to an optimal solution (if it exists), but after a finite number of iterations a strongly polynomial rounding procedure [2,16] generates an exact solution. This section is based on the paper of Terlaky [7], and Part I and the Appendix of Roos *et al.* [2].

Duality and the Self-Dual Embedding Model

We consider the general LP problem (P) and its dual (D) in the standard canonical form as defined in the section “LP Duality and Condition Numbers.” Theorem 1, the weak duality theorem and its corollary leads to the optimality conditions that are represented as the linear inequality system (FP). By introducing slack variables, and by homogenizing the inequality system, the Goldman–Tucker model [9,17] is obtained.

$$\begin{array}{rclcl} Ax - \tau b - z & = & 0, & x \geq 0, & z \geq 0 \\ -A^T y & + \tau c & -s & = & 0, & y \geq 0, & s \geq 0 \\ b^T y - c^T x & & -\rho & = & 0, & \tau \geq 0, & \rho \geq 0. \end{array} \quad (3)$$

It is easy to verify that for any solution (y, x, τ, z, s, ρ) of the Goldman–Tucker system (3) $\tau \rho > 0$ cannot hold. Further, any optimal pair (x, y) of problems (P) and (D) with zero duality gap is a solution of the Goldman–Tucker system with $\tau = 1$ and $\rho = 0$. We are looking for nontrivial solutions of this system with $\tau > 0$, because those give primal and dual optimal solutions $(\frac{x}{\tau}, \frac{y}{\tau})$ with zero duality gap, as $\tau > 0$ implies $\rho = 0$.

On the other hand, if the Goldman–Tucker system admits a feasible solution $(\hat{y}, \hat{x}, \hat{\tau}, \hat{z}, \hat{s}, \hat{\rho})$ with $\hat{\tau} = 0$ and $\hat{\rho} > 0$, then we may conclude that either of (P) or (D), or both of (P) and (D), are infeasible. Summarizing these results, we have the following theorem.

Theorem 7. *Let a primal dual pair (P) and (D) of LP problems be given. The following statements hold for the solutions of the Goldman–Tucker system (3).*

1. *Any optimal pair (x, y) of (P) and (D) with zero duality gap is a solution of the corresponding Goldman–Tucker system with $\tau = 1$.*
2. *If (y, x, τ, z, s, ρ) is a solution of the Goldman–Tucker system then either $\tau = 0$, or $\rho = 0$, or both, that is, $\tau \rho > 0$ cannot happen.*
3. *Any solution (y, x, τ, z, s, ρ) of the Goldman–Tucker system, where $\tau > 0$ and $\rho = 0$, gives a primal and dual optimal pair $(\frac{x}{\tau}, \frac{y}{\tau})$ with zero duality gap.*
4. *If the Goldman–Tucker system admits a feasible solution $(\hat{y}, \hat{x}, \hat{\tau}, \hat{z}, \hat{s}, \hat{\rho})$ with $\hat{\tau} = 0$ and $\hat{\rho} > 0$, then we may conclude that either (P), or (D), or both of them are infeasible.*

IPMs lead us to a solution of the Goldman–Tucker system where either $\tau > 0$ or $\rho > 0$. Thus, the IPM approach ensures $\tau + \rho > 0$. Now we give a simple form of the Goldman–Tucker model. Let

$$Mu \geq 0, \quad u \geq 0, \quad w(u) = Mu, \quad (4)$$

where

$$u = \begin{pmatrix} y \\ x \\ \tau \end{pmatrix}, \quad w(u) = \begin{pmatrix} z \\ s \\ \rho \end{pmatrix}, \quad \text{and} \\ M = \begin{pmatrix} 0 & A & -b \\ -A^T & 0 & c \\ b^T & -c^T & 0 \end{pmatrix}$$

is a skew-symmetric $n \times n$ matrix, that is, $M^T = -M$ and $n = m + \ell + 1$. The Goldman–Tucker Theorem [2,9,17] states that system (4) admits a *strictly complementary* solution.

Theorem 8 [Goldman–Tucker]. *System (4) has a strictly complementary feasible solution, i.e., a solution for which $uw(u) = 0$ and $u + w(u) > 0$.*

This theorem ensures that either case 3 or case 4 of Theorem 7 must occur when one solves the Goldman–Tucker system of LP. This is in fact the strong duality theorem of LP.

Theorem 9 [Strong duality for LP]. *Let a primal and dual LP problem be given. Exactly one of the following statements hold:*

- Both (P) and (D) are feasible, and there are optimal solutions x^* and y^* such that $c^T x^* = b^T y^*$.
- Either problem (P), or (D), or both of them are infeasible.

The Skew-Symmetric Self-Dual Embedding Model. Problem (4) is a homogeneous feasibility problem, and we transform it into an equivalent problem, which satisfies the interior point condition (IPC), that is, that admits a solution where $u > 0$ and $w(u) > 0$. This happens by embedding the problem and defining

an appropriate nonnegative vector q that will be both the right-hand side and the objective vector in the larger LP problem.

Let us take $u = w(u) = e$. These vectors are positive, but they do not satisfy the equality conditions in Equation (4). Let us further define the error vector r obtained this way by

$$r := e - Me \quad \text{and let} \quad \lambda := n + 1.$$

Then we have

$$\begin{pmatrix} M & r \\ -r^T & 0 \end{pmatrix} \begin{pmatrix} e \\ 1 \end{pmatrix} + \begin{pmatrix} 0 \\ \lambda \end{pmatrix} = \begin{pmatrix} Me + r \\ -r^T e + \lambda \end{pmatrix} = \begin{pmatrix} e \\ 1 \end{pmatrix}.$$

Hence, the following problem

$$\begin{aligned} \min \left\{ \lambda \vartheta : \begin{pmatrix} M & r \\ -r^T & 0 \end{pmatrix} \begin{pmatrix} u \\ \vartheta \end{pmatrix} + \begin{pmatrix} w \\ v \end{pmatrix} \right. \\ \left. = \begin{pmatrix} 0 \\ \lambda \end{pmatrix}; \begin{pmatrix} u \\ \vartheta \end{pmatrix}, \begin{pmatrix} w \\ v \end{pmatrix} \geq 0 \right\} \quad (\overline{\text{SP}}) \end{aligned}$$

satisfies the IPC because the all-one vector is feasible for this problem. This problem is a self-dual skew-symmetric LP problem, because by introducing the notation

$$\overline{M} = \begin{pmatrix} M & r \\ -r^T & 0 \end{pmatrix}, \quad \overline{u} = \begin{pmatrix} u \\ \vartheta \end{pmatrix}, \quad \text{and} \quad \overline{q} = \begin{pmatrix} 0 \\ \lambda \end{pmatrix},$$

one can write problem $(\overline{\text{SP}})$ as

$$\min \left\{ \overline{q}^T \overline{u} : \overline{M} \overline{u} \geq -\overline{q}, \overline{x} \geq 0 \right\}. \quad (\text{SPe})$$

Finding a strictly complementary solution to (4) is equivalent to finding a strictly complementary optimal solution to problem (SPe). This claim is valid, because Equation (SPe) satisfies the IPC and it admits a strictly complementary optimal solution. As the objective function is just a constant multiple of ϑ , and the optimal value is zero, ϑ must be zero in any optimal solution. Having a strictly complementary solution of Equation (SPe), we either have an optimal solution of the embedded LP problem, or we can conclude that the LP problem does not have an optimal solution.

Basic Properties of the Skew-Symmetric Self-Dual Model. We continue to study our skew-symmetric self-dual embedding problem (SPe) while utilizing that the IPC holds for this LP problem. For ease of discussion let us simplify our notation, so the embedding problem (SPe) can be given as

$$\min \left\{ q^T u : Mu \geq -q, u \geq 0 \right\}, \quad (\text{SP})$$

where the matrix $M \in \mathbb{R}^{n \times n}$ is skew-symmetric, $0 \leq q \in \mathbb{Z}^n$, and problem (SP) satisfies the IPC, i.e., there exists an $u > 0$ with $Mu > 0$. The set of *feasible* and the set of *optimal* solutions of (SP) are denoted by

$$\begin{aligned} \text{SP} &:= \{u : u \geq 0, Mu \geq -q\} \quad \text{and} \\ \text{SP}^* &:= \{u : u \geq 0, Mu + q = w(u) \geq 0, \\ &\quad uw(u) = 0\}. \end{aligned}$$

The only nontrivial result that one needs to prove is the existence of a strictly complementary solution. The IPC implies this result by implying the existence of the *central path* [18–21] of problem (SP), which plays a crucial role in path-following IPMs.

Definition 2. Let the IPC be satisfied. The *central path* of problem (SP) is defined as the set of solutions

$$\begin{aligned} \{(u(\mu), w(u(\mu))) : Mu + q = w, \quad uw = \mu e, \\ u > 0, \quad \text{for some } \mu > 0\}. \end{aligned}$$

If no confusion is possible, instead of $w(u(\mu))$, the notation $w(\mu)$ will be used. The following key theorem establishes the existence of the central path. For an elementary proof—using only calculus—the reader is referred to Terlaky [7].

Theorem 10. *The next statements are equivalent.*

- (i) (SP) satisfies the interior point condition;
- (ii) For each $0 < \mu \in \mathbb{R}$ there exists a unique solution $(u(\mu), w(\mu)) > 0$ such that

$$Mu + q = w$$

$$uw = \mu e.$$

Analogous to the definitions in the section titled “Optimal Partition”, the *optimal partition* $(\mathbf{B}, \mathbf{N})$ is given by

$$\begin{aligned} \mathbf{B} &:= \{i : u_i > 0, \text{ for some } u \in \text{SP}^*\}, \\ \mathbf{N} &:= \{i : w(u)_i > 0, \text{ for some } u \in \text{SP}^*\}. \end{aligned}$$

The central path converges to a strictly complementary optimal solution, that is, if $u^* = \lim_{\mu \rightarrow 0} u(\mu)$ then $u^* w(u^*) = 0$ and $u^* + w(u^*) > 0$, and thus $\mathbf{B} \cup \mathbf{N} = \{1, \dots, n\}$. By using the embedding model, this result implies the Goldman–Tucker theorem (Theorem 8) for the general LP problem.

Theorem 11. *If the IPC holds then there exists an optimal solution u^* and $w^* = w(u^*)$ of problem (SP) such that $u^* w^* = 0$, $u_{\mathbf{B}}^* > 0$, $w_{\mathbf{N}}^* > 0$ and $u^* + w^* > 0$.*

A key result in this respect is that the central path converges to a unique point, the so-called *analytic center* [21] of the optimal set SP^* . Let $\bar{u} \in \text{SP}^*$, $\bar{w} = w(\bar{u})$ maximize the product $\prod_{i \in \mathbf{B}} u_i \prod_{i \in \mathbf{N}} w_i$ over $u \in \text{SP}^*$. Then $\bar{u}$ is called the *analytic center* of SP^* .

Theorem 12. *The limit point u^* of the central path is the analytic center of SP^* .*

Identifying the Optimal Partition. As in the section titled “Optimal Partition” we define a condition number of problem (SP), which characterizes the magnitude of the nonzero variables on the optimal set SP^* . Let

$$\sigma^u := \min_{i \in \mathbf{B}} \max_{u \in \text{SP}^*} \{u_i\} \quad \sigma^w := \min_{i \in \mathbf{N}} \max_{u \in \text{SP}^*} \{w(u)_i\}.$$

Then the *condition number* of problem (SP) is defined as

$$\sigma = \min\{\sigma^u, \sigma^w\} = \min_i \max_{u \in \text{SP}^*} \{u_i + w(u)_i\}.$$

As before, if M and q are integral and all the columns of M are nonzero. By using the

notation $\pi(M) = \prod_{i=1}^n \|M_i\|$, one can give an easily computable lower bound for σ as

$$\sigma \geq \frac{1}{\pi(M)}. \quad (5)$$

The Size of the Variables along the Central Path. By using the condition number σ , one can derive lower and upper bounds for the variables along the central path.

Lemma 5. *Let $(\mathbf{B}, \mathbf{N})$ be the optimal partition of problem (SP). For each positive μ one has*

$$u_i(\mu) \geq \frac{\sigma}{n} \quad i \in \mathbf{B}, \quad u_i(\mu) \leq \frac{n\mu}{\sigma} \quad i \in \mathbf{N},$$

$$w_i(\mu) \leq \frac{n\mu}{\sigma} \quad i \in \mathbf{B}, \quad w_i(\mu) \geq \frac{\sigma}{n} \quad i \in \mathbf{N}.$$

Identifying the Optimal Partition. For sufficiently small μ , the bounds presented in Lemma 5 enable us to identify the optimal partition $(\mathbf{B}, \mathbf{N})$. One just has to calculate the μ value that ensures that the coordinates going to zero are smaller than the coordinates that stay larger than $\frac{\sigma}{n}$. One can easily verify that having $\mu < \frac{\sigma^2}{n^2}$ and a central solution $u(\mu) \in SP$, the optimal partition $(\mathbf{B}, \mathbf{N})$ can be identified. Note that these results can be generalized to the case when a vector (u, w) is not on, but just in a neighborhood of the central path. For proofs the interested reader is referred to Roos *et al.* [2].

Rounding to an Exact Solution. A strictly complementary solution can be identified by moving along the central path as $\mu \rightarrow 0$. In fact, we do not have to do that; we can stop at a sufficiently small $\mu > 0$, and round-off the current “almost optimal” solution to a strictly complementary optimal one. We need some new notation. Let $\omega := \|M\|_\infty = \max_{1 \leq i \leq n} \sum_{j=1}^n |M_{ij}|$ and $\pi := \pi(M) = \prod_{i=1}^n \|M_i\|$.

Lemma 6. *Let M and q be integral and all the columns of M be nonzero. If $(u, w) := (u(\mu), w(u(\mu)))$ is a central solution with*

$$u^T s = n\mu \leq \frac{\sigma^2}{n^{\frac{3}{2}}(1+\omega)^2\pi},$$

which certainly holds if

$$n\mu \leq \frac{1}{n^{\frac{3}{2}}(1+\omega)^2\pi^3},$$

then by a simple rounding procedure a strictly complementary optimal solution can be found in $\mathcal{O}(n^3)$ arithmetic operations.

Note that this rounding result can also be generalized to the situation when a vector (u, w) is not on, but just in a certain neighborhood of the central path. For details the reader is referred again to Roos *et al.* [2]. This result makes it clear that when one solves an LP problem by using an IPM, the iterative process can be stopped in a proper neighborhood of the central path at a sufficiently small value of μ , and at that point one can round-off to a strictly complementary optimal solution.

Optimal Basis Identification. It is well known that simplex methods provide an optimal basis. A reassuring fact is that having a complementary optimal solution pair, an optimal basis can be identified in strongly polynomial time, in at most n pivots; thus, an interior optimal solution pair allows efficient identification of an optimal basis. For a proof the reader may consult Roos *et al.* [2], Megiddo [22], and Ye [23].

Summary of the Theoretical Results

Let us summarize the results for the general LP problem in canonical form

$$\min \left\{ c^T x : Ax - z = b, x \geq 0, z \geq 0 \right\}, \quad (P)$$

$$\max \left\{ b^T y : A^T y + s = c, y \geq 0, s \geq 0 \right\}, \quad (D)$$

where for convenience the slack variables are already included in the problem formulation.

- In the section titled “Duality and the Self-Dual Embedding Model” we have seen that to solve the LP problem it is

sufficient to find a strictly complementary solution to the Goldman–Tucker model (4).

- This *homogeneous* system always admits the zero solution; however, to get a solution for the original problems we need a strictly complementary solution pair for which $\tau + \rho > 0$ holds.
- The Goldman–Tucker model can be transformed into a skew-symmetric self-dual problem (SP) satisfying the IPC.
- If problem (SP) satisfies the IPC then
 - the central path exists (Theorem 10);
 - the central path converges to a strictly complementary solution (Theorem 11);
 - the central path converges to the analytic center of the optimal set (Theorem 12);
 - if the problem data is integral and a solution on the central path with a sufficiently small μ is given, then the optimal partition and an exact strictly complementary optimal solution (Lemma 6) can be found.
- If (x^*, z^*) is optimal for (P) and (s^*, y^*) for (D) , then $(y^*, x^*, 1, z^*, s^*, 0)$ is a solution for the Goldman–Tucker model with the requested property $\tau + \rho > 0$ (Theorem 7).
- Any solution of the Goldman–Tucker model (y, x, τ, z, s, ρ) with $\tau > 0$ yields an optimal solution pair (scale the variables (x, z) and (y, s) by $\frac{1}{\tau}$) for LP (Theorem 7).
- Any solution of the Goldman–Tucker model (y, x, τ, z, s, ρ) with $\rho > 0$ provides a certificate of primal or dual infeasibility (Theorem 7).
- If $\tau = 0$ in every solution (y, x, τ, z, s, ρ) then (P) and (D) have no optimal solutions.
- From any complementary optimal pair of primal-dual solutions, an optimal basis can be identified in strongly polynomial time

In the next section a generic IPM is presented and the complexity of some variants is discussed.

A General Scheme of IP Algorithms for Linear Optimization

In this section we briefly review the main elements of IPMs. For easy reference to the majority of the literature, the algorithmic concepts are presented for the standard form of LP problems:

$$\min \{c^T x : Ax = b, x \geq 0\} \quad (P_s)$$

$$\max \{b^T y : A^T y + s = c, y \geq 0\}. \quad (D_s)$$

For this form, for any interior feasible $x, s > 0$ solution, the Newton system for the central path equations

$$\begin{array}{rcl} Ax & = & b \\ A^T y & +s & = c \\ xs & = & \mu e \end{array} \quad (6)$$

is given as

$$\begin{array}{rcl} A\Delta x & = & 0 \\ A^T \Delta y & +\Delta s & = 0 \\ s\Delta x & +x\Delta s & = \mu e - xs. \end{array} \quad (7)$$

Assuming that $\text{rank}(A) = m$, where A is an $m \times n$ matrix, and $x, s > 0$, the above Newton system (7) has a unique solution. Having determined this unique solution, a possibly damped Newton step can be made as

$$x := x + \alpha \Delta x, \quad s := s + \alpha \Delta s.$$

IPMs make full or damped Newton steps at each iterations, and the process is controlled by careful selection of the step length and the targeted central path parameter value μ or, in broader sense, the right-hand side of the third Newton equation. A key tool in this process is the choice of a proximity measure that allows to quantify the distance from the central path and ensure that the iterates remain positive.

Proximity Measures. We have seen that the central path leads to a specific strictly complementary solution, to the analytic center of the set of optimal solutions. However, due to the nonlinearity of the equation system determining the central path, the iterates cannot stay on the central path, even if one uses

the embedding model and the initial interior point was on the central path. For this reason we need some proximity measures that allow us to control the Newton process and keep the iterates in a proper neighborhood of the central path. These proximity measures depend on the current primal-dual iterate x and s , and the central path parameter value μ , that is either chosen independent of x and s or as $\mu = x^T s / n$. The goal is to quantify how far the iterate is from the point corresponding to μ on the central path. In general the proximity measure is denoted by $\delta(x, s, \mu)$.

Various centrality measures were developed in the literature of IPMs, see the books [2,15,23–26]. Here we present just two of them. Both of the proximity measures allow us to design polynomial IPMs. Observe that on the central path all the coordinates of the vector xs are equal. This observation indicates that the proximity measure

$$\delta_c(xs) := \frac{\max(xs)}{\min(xs)},$$

where $\max(xs)$ and $\min(xs)$ denote the largest and smallest coordinate of the vector xs , is an appropriate measure of centrality. One has $\delta_c(xs) \geq 1$, and the larger the value of $\delta_c(xs)$ is, the further the iterate is from the central path. If $\delta_c(xs) = 1$, then the current solution $(x, s) = (x(\mu), s(\mu))$, with $\mu = x^T s / n$, is on the central path. Another proximity measure, extensively used in Roos *et al.* [2] is

$$\delta_0(xs, \mu) := \frac{1}{2} \left\| \left(\frac{xs}{\mu} \right)^{\frac{1}{2}} - \left(\frac{\mu}{xs} \right)^{\frac{1}{2}} \right\|.$$

One has $\delta_0(xs, \mu) \geq 0$, and the larger the value of $\delta_0(xs)$ is, the further the iterate is from the target point on the central path. If $\delta_0(xs, \mu) = 0$, then the current solution is on the central path.

A Generic Interior Point Algorithm. Algorithm 1 gives a general framework for a large family polynomial time IPMs.

Algorithm 1. Generic Interior Point Newton Algorithm

Input:

A proximity parameter γ ; an accuracy parameter $\varepsilon > 0$;
a variable step length α ; update parameter $0 < \theta < 1$;
a feasible (x^0, s^0) and $\mu^0 > 0$ s.t. $\delta(x^0, s^0, \mu^0) \leq \gamma$.

begin

$x := x^0$; $s := s^0$; $\mu := \mu^0$;

while $n\mu \geq \varepsilon$ **do**

begin

$\mu := (1 - \theta)\mu$;

while $\delta(x, s, \mu) \geq \gamma$ **do**

begin

solve the Newton system (7);

choose the damping factor α ;

$x := x + \alpha \Delta x$;

$s := s + \alpha \Delta s$;

end

end

end

Proper choices of the parameters allow to prove polynomial iteration complexity of the resulting algorithm. Here we present three sets of choices that give polynomial IPMs. For complexity proofs, see for example, Roos *et al.*

[2] and the papers cited therein. To specify a concrete algorithm the following choices need to be made:

- choose the proximity measure $\delta(x, s, \mu)$, and the proximity parameter γ ,

- choose the update scheme for μ , and specify the step length for the Newton step.

The first IPM, that also enjoys the best possible iteration complexity bound, is a *primal-dual algorithm with full Newton steps* [2]. Let us make the following choices:

$$\begin{aligned} \delta(x, s, \mu) &:= \delta_0(xs, \mu); \quad \mu^0 := 1; \\ \theta &:= \frac{1}{2\sqrt{n}}; \quad \gamma = \frac{1}{\sqrt{2}}; \alpha = 1. \end{aligned}$$

Theorem 13 [2, Theorem II.52]. *With the given parameter set, the full Newton step algorithm requires at most*

$$\left\lceil 2\sqrt{n} \log \frac{n}{\varepsilon} \right\rceil$$

iterations to produce a feasible solution (x, s) such that $\delta_0(xs, \mu) \leq \gamma$ and $n\mu \leq \varepsilon$.

The second IPM is a *primal-dual large-update algorithm* [2]. The choices are

$$\begin{aligned} \delta(x, s, \mu) &:= \delta_0(xs, \mu); \\ \mu^0 &:= 1; \quad 0 < \theta < \frac{n}{n + \sqrt{n}}; \\ \gamma &= \frac{\sqrt{R}}{2\sqrt{1 + \sqrt{R}}}, \text{ where } R := \frac{\theta\sqrt{n}}{1 - \theta}; \end{aligned}$$

and α is the result of a line search, when along the search direction the primal-dual logarithmic barrier function $\frac{x^T s}{\mu} - \sum_{i=1}^n \log \frac{x_i s_i}{\mu}$ is minimized.

Theorem 14 [2, Theorem II.74]. *With the given parameter set the primal-dual large-update algorithm requires at most*

$$\left\lceil \frac{1}{\theta} \left[2 \left(1 + \sqrt{\frac{\theta\sqrt{n}}{1 - \theta}} \right)^4 \right] \log \frac{n}{\varepsilon} \right\rceil$$

iterations to produce a feasible solution (x, s) , such that $\delta_0(xs, \mu) \leq \tau$ and $n\mu \leq \varepsilon$.

When we choose $0 < \theta < 1$ as a constant independent of n , for example, $\theta = 0.9$, then the complexity becomes $\mathcal{O}(n \log \frac{n}{\varepsilon})$, while $\theta = \frac{\nu}{\sqrt{n}}$,

with any fixed positive value ν gives a complexity of $\mathcal{O}(\sqrt{n} \log \frac{n}{\varepsilon})$.

The third IPM is the *Dikin step algorithm* studied for example, in Roos *et al.* [2]. This is one of the simplest IPMs, with an extremely elementary complexity analysis. The price for simplicity is that the polynomial complexity result is not the best possible. For this algorithm we choose $\delta(x, s, \mu) := \delta_c(xs)$. Recall that this measure is always larger than or equal to 1. Further let $\gamma = 2$, $\mu^0 := 0$ imply that μ stays equal to zero, thus θ is irrelevant. The Newton step $(\Delta x, \Delta s)$ is the solution of Equation (7), when the right-hand side of the last equation is replaced by $-\frac{x^2 s^2}{\|xs\|}$, and finally let $\alpha = \frac{1}{2\sqrt{n}}$.

Theorem 15 [2, Theorem I.27]. *The Dikin step algorithm requires not more than*

$$\left\lceil 2n \log \frac{n}{\varepsilon} \right\rceil$$

iterations to produce a feasible solution (x, s) for $(\overline{\text{SP}})$ such that $\delta_c(xs) \leq 2$ and $n\mu \leq \varepsilon$.

EXTENSIONS

IPMs are developed much beyond LP. The books [23–25, 27, 28] discuss extensions of IPMs for classes of nonlinear problems. IPMs also provide polynomial time algorithms for second-order cone and semidefinite optimization problems that both have numerous interesting applications, not only in such traditional areas as combinatorial optimization [29] and control [30, 31], but also in various areas of engineering, including structural [30, 32] and electrical engineering [33, 34]. For surveys on algorithmic and complexity issues the reader may consult [23, 27, 35–40].

INTRODUCTION

The evaluation of rare-event probabilities can pose significant challenges for simulation. To illustrate, let γ be the probability of a rare event. The standard way to estimate γ is to conduct n i.i.d. replications. Assuming that the outcome of each replication is either a 1 (denoting the occurrence of the rare event) or a 0 (denoting the nonoccurrence of the event), then the standard estimator $\hat{\gamma}$ is the number of observed occurrences divided by the number of replications. This is a binomial random variable with mean γ and variance

$$\text{Var}[\hat{\gamma}] = \frac{\gamma(1-\gamma)}{n} \approx \frac{\gamma}{n}.$$

Although $\text{Var}[\hat{\gamma}]$ gets smaller as the rare-event probability γ decreases, it is more useful to consider the *relative error* of the estimator, defined here as the standard deviation divided by the actual value

$$\text{Relative error} \equiv \frac{\sqrt{\text{Var}[\hat{\gamma}]}}{\gamma} \approx \frac{\sqrt{\gamma/n}}{\gamma} = \frac{1}{\sqrt{\gamma n}}. \quad (1)$$

The relative error can be interpreted as the root mean square error of the estimator $\hat{\gamma}$ divided by the root mean square error of the trivial estimator that always returns the

value zero. If $\hat{\gamma}$ is approximately normally distributed, the relative error provides a measure of the size of the confidence interval relative to the value being estimated (though “approximately normal” is not typical in the context of rare events). The basic problem is that the relative error increases as the rare-event probability gets smaller. More generally, the required number of replications grows inversely with γ . It also grows inversely with the square of the relative error. Table 1 shows examples of the required time to achieve a given relative error for a specified rare-event probability (assuming simulation speeds of 1 and 1000 replications per second). This illustrates that standard simulation may be impractical for many rare-event problems.

Rare-event simulation is used in many application areas, including finance and insurance where the rare event could be a large financial gain or loss, communication systems where the rare event could be the loss of important information, power systems where the rare event could be a major power outage, network reliability where the rare event could mean that certain nodes in the network are disconnected, nuclear physics where the rare event could be that particles cross a given protection shield, and aviation safety where the rare event could be an aircraft collision. It is also encountered in computer graphics (image synthesis by Monte Carlo methods), computational statistics, computational physics, computational biology, military applications, and so on. The goal is not always to estimate the probability of a rare event. It can be to estimate the mathematical expectation of a random variable that is strongly affected by rare events. But the main ideas and methods are basically the same as when the goal is to estimate the rare-event probability itself.

There are two main approaches for improving the efficiency of rare-event simulations—importance sampling (IS) and splitting. The idea of IS is to change the

Table 1. Computer Time Needed to Achieve a Specified Relative Error (Standard Simulation)

γ	Desired Relative Error			
	1 Replication per Second		1000 Replications per Second	
	100%	10%	100%	10%
10^{-3}	17 min	1 d	1 s	2 min
10^{-5}	1 d	4 mo	2 min	3 h
10^{-7}	4 mo	32 yr	3 h	12 d
10^{-9}	32 yr	3169 yr	12 d	3 yr

underlying sampling distribution so that rare events are more likely. The idea of splitting is to create separate copies of the simulation whenever the simulation gets “close” to the rare event of interest, effectively multiplying promising runs that are more likely to reach the rare event. Splitting is useful for systems that tend to take many incremental steps on the path to the rare event. IS is also useful for systems that tend to take a small number of “catastrophic jumps” to the rare event.

This article does not give a comprehensive literature review but simply offers some suggestions for further reading: The book edited by Rubino and Tuffin [1] contains survey chapters on a wide range of topics and applications in rare-event simulation. Much of the material in this article can be found in more elaborate form in the first three chapters of that book. More extensive coverage and lists of references on IS can be found in Heidelberger [2], Bucklew [3], Juneja and Shahabuddin [4], and Amussen and Glynn [5]. Good introductory references on splitting include Garvels [6] and L’Ecuyer *et al.* [7].

IMPORTANCE SAMPLING

We first consider IS as applied to a static problem. Let X be a random variable in d -dimensional space with density function f . Let $\mathcal{R}$ denote a rare-event set in $\mathbb{R}^d$. Let $\gamma = \Pr\{X \in \mathcal{R}\}$. The standard way to estimate γ using Monte Carlo simulation is to generate independent samples $X_1, \dots, X_n$ from the density f and to estimate γ by

$$\hat{\gamma} = \frac{1}{n} \sum_{i=1}^n I_{\mathcal{R}}(X_i), \quad (2)$$

where $I_{\mathcal{R}}(x) = 1$ if $x \in \mathcal{R}$ and 0 otherwise. If γ is very small, the relative error $(\gamma n)^{-1/2}$ of this estimator can be very large. In fact, $\hat{\gamma}$ may turn out to be 0, in which case a confidence interval on γ computed in a standard way would also have zero width.

The idea of IS is to sample values from a different density function g rather than from the original density f . Presumably, the new density g is chosen so that the rare event is more likely to occur. Naturally, some adjustment must be made to correct for sampling from a different density function. The procedure is to generate samples $Y_1, \dots, Y_n$ from the density g and to estimate γ by

$$\hat{\gamma} = \frac{1}{n} \sum_{i=1}^n \frac{f(Y_i)}{g(Y_i)} I_{\mathcal{R}}(Y_i) = \frac{1}{n} \sum_{i=1}^n L(Y_i) I_{\mathcal{R}}(Y_i), \quad (3)$$

where $L(y) \equiv f(y)/g(y)$ is the *likelihood ratio* of the two densities. To show that $\hat{\gamma}$ is unbiased, observe that

$$\begin{aligned} E \left[\frac{f(Y_i)}{g(Y_i)} I_{\mathcal{R}}(Y_i) \right] &= \int \frac{f(y)}{g(y)} I_{\mathcal{R}}(y) g(y) dy \\ &= \int I_{\mathcal{R}}(x) f(x) dx = \gamma. \end{aligned}$$

It is assumed that $g(y) > 0$ whenever $f(y) I_{\mathcal{R}}(y) > 0$.

A key objective is to find a change of measure that achieves significantly lower variance for the IS estimator in Equation (3) compared with the standard estimator in Equation (2). In other words, we seek to minimize the variance of $I_{\mathcal{R}}(Y_i) L(Y_i)$. In fact, it is possible to find a change of measure such

that $I_{\mathcal{R}}(Y_i)L(Y_i)$ has zero variance. This is achieved by the *optimal change of measure*

$$g(y) = \frac{1}{\gamma} f(y) I_{\mathcal{R}}(y) \quad \text{and} \quad L(y) = \frac{\gamma}{I_{\mathcal{R}}(y)}.$$

The optimal change of measure g has two key properties: (i) It is zero outside of $\mathcal{R}$, and (ii) it is proportional to the original density f inside of $\mathcal{R}$. The first property implies that $I_{\mathcal{R}}(Y_i)$ (sampled from the density g) is always 1. The second property implies that $L(Y_i) = f(Y_i)/g(Y_i)$ is always the same constant. Together, these two properties imply that $L(Y_i)I_{\mathcal{R}}(Y_i)$ has zero variance.

Practically speaking, finding the optimal change of measure requires knowing the rare-event probability γ , which eliminates the need for simulation in the first place. But the optimal change of measure is still useful in the sense that it provides a guideline for choosing a good change of measure. A good change of measure is mostly concentrated on the rare-event set $\mathcal{R}$ and is roughly proportional to the original density f on this set. Alternatively, $L(y)$ is small and roughly constant when $y \in \mathcal{R}$.

In the following examples, γ is known *a priori*; so, there is no need for simulation. We use these small examples just to illustrate the basic ideas.

Example (See [8]). Let X be an exponential random variable with density $f(x) = \lambda e^{-\lambda x}$, and $\mathcal{R} = \{x | x \geq T\}$, so $\gamma = e^{-\lambda T}$. The optimal change of measure is $g(y) = \lambda e^{-\lambda y} / e^{-\lambda T}$ for $y \geq T$ and $g(y) = 0$ elsewhere. But suppose for the sake of example that we only allow changes of measure that are linear scalings of the original density. In other words, the new sampling density is restricted to be exponential with a different parameter μ , namely, $g(y) = \mu e^{-\mu y}$. The likelihood ratio is

$$L(y) = \frac{\lambda e^{-\lambda y}}{\mu e^{-\mu y}} = (\lambda/\mu) e^{-(\lambda-\mu)y}.$$

Minimizing the variance of the IS estimator $\hat{\gamma}$ in Equation (3) is equivalent to minimizing the second moment of $L(Y_i)I_{\mathcal{R}}(Y_i)$

$$\begin{aligned} E[[L(Y_i)I_{\mathcal{R}}(Y_i)]^2] &= E[L^2(Y_i)I_{\mathcal{R}}(Y_i)] \\ &= \int_T^\infty (\lambda/\mu)^2 e^{-2(\lambda-\mu)y} g(y) dy \\ &= (\lambda^2/\mu) \int_T^\infty e^{-(2\lambda-\mu)y} dy \\ &= \frac{\lambda^2}{\mu(2\lambda-\mu)} e^{-(2\lambda-\mu)T}. \end{aligned} \quad (4)$$

The integral is finite and the equality is true only when $2\lambda - \mu > 0$; so, $\text{Var}[\hat{\gamma}]$ is finite only for $0 < \mu < 2\lambda$. In particular, $\text{Var}[\hat{\gamma}] \rightarrow \infty$ as $\mu \rightarrow 0$. This shows that simply forcing the samples to take on large values (i.e., by letting μ to be a small number) is not necessarily a good idea. Although a small value of μ makes $I_{\mathcal{R}}(Y_i)$ more likely to equal one, it may drastically increase the likelihood function $L(Y_i)$ for some $Y_i \in \mathcal{R}$ by making its denominator $g(Y_i)$ (the new density) much too small, thus increasing the overall variance of $I_{\mathcal{R}}(Y_i)L(Y_i)$. This highlights a key difficulty of IS in general: one must make sure that the probabilities (or densities) of sample realizations that contribute to the expectation being estimated are never reduced too much, because otherwise the estimator may take huge values occasionally and will then have a large variance. In typical multivariate situations, this can be very difficult to take care of.

Figure 1 shows the ratio of the IS-estimator variance and the standard-estimator variance as a function of the change-of-measure parameter μ . The figure shows results for two different problems ($T = 3$ and $T = 5$) with $\lambda = 1$. Intuitively, as might be expected, choosing a value of μ larger than λ (i.e., forcing the samples to take on smaller values) makes the IS estimator worse than standard simulation. Choosing a value of μ smaller than λ (i.e., forcing the samples to take larger values) typically makes the IS estimator better than standard simulation. However, μ cannot be too small, otherwise the variance can be much worse than standard simulation. This illustrates the fact that without being sufficiently careful, it is easy to choose an IS estimator that is much worse than the standard estimator.

It is easily verified that the value of μ that minimizes the second moment in Equation (4)

Figure 1. Dependence of variance ratio ($\text{Var}[L(Y_i)I_{\mathcal{R}}(Y_i)]/\text{Var}[I_{\mathcal{R}}(X_i)]$) as a function of μ .

is $\mu^* = \lambda + 1/T - (\lambda^2 + 1/T^2)^{1/2}$. This value is always smaller than λ and $1/T$. Also, $\mu^*T \rightarrow 1$ when $T \rightarrow \infty$. The squared relative error, namely, (Equation (4) $-\gamma^2/\gamma^2$, with the optimal μ is

$$\begin{aligned} \frac{\lambda^2}{\mu^*(2\lambda - \mu^*)} e^{\mu^*T} - 1 &\sim \frac{e}{2} \lambda T - 1 \\ &= \frac{e}{2} \ln(1/\gamma) - 1, \end{aligned}$$

where $u(\cdot) \sim v(\cdot)$ if $u(T)/v(T) \rightarrow 1$ as $T \rightarrow \infty$. Although the squared relative error increases when $\gamma \rightarrow 0$ (or $T \rightarrow \infty$), it only increases at a logarithmic speed in $1/\gamma$ (or linearly in T). In contrast, with crude Monte Carlo, it increases linearly in $1/\gamma$ (or exponentially in T). For example, suppose that $\lambda = 1$ and $T = 20$, so $\gamma = e^{-20}$. With crude Monte Carlo, it would take about $n \geq 100 \cdot (1/\gamma) \approx 5 \times 10^{10}$ replications to get a relative error below 10%. With the given IS scheme, it would take about $n \geq 100 \cdot [(e/2) \ln(1/\gamma) - 1] \approx 2618$ replications.

Very similar examples can be constructed with other distributions, for example a normal or a Poisson distribution for which we want to estimate the (small) probability that the random variable exceeds a given threshold.

With the IS scheme in the previous example, the relative error was still increasing in T , but more slowly than with crude

Monte Carlo. Ideally, we would like to have *bounded relative error*, meaning that the relative error remains bounded as $T \rightarrow \infty$, or more generally as $\gamma \rightarrow 0$. In this case, a fixed number of runs permits one to achieve a desired relative error regardless of how rare the event is. Here, we have a slightly weaker condition called *logarithmic efficiency* (or sometimes *asymptotic optimality*), namely, that

$$\lim_{\gamma \rightarrow 0} \frac{\ln E[\hat{\gamma}^2]}{\ln \gamma^2} = 1. \quad (5)$$

This means that the second moment of the estimator and the square of the mean go to zero at the same exponential rate when $\gamma \rightarrow 0$. This is almost as good as bounded relative error, and it can be obtained in a much broader range of situations. There are also situations where one can achieve *vanishing relative error* under IS; this means that the relative error converges to 0 when $\gamma \rightarrow 0$; so rarer events are easier to estimate [9,10]. These asymptotic properties of the second (relative) moment also generalize to moments of any order [10]. For example, *logarithmic efficiency of order k* means that Equation (5) holds with 2 replaced by k .

Now we consider IS applied to discrete-time Markov chains (DTMCs). Let $\mathcal{R}$ denote a set of rare-event states and let $\mathcal{O}$ denote a set of “other” terminating states. The problem is to estimate the probability γ that a

Markov chain enters $\mathcal{R}$ before $\mathcal{O}$. The idea of IS is to change the transition probabilities to reduce the variance of the rare-event estimator. Specifically, let $p(x, y)$ be the transition probability from x to y in the original chain, and let $p'(x, y)$ be the transition probability from x to y in a modified chain. The only restriction is that $p'(x, y)$ must be positive whenever $p(x, y)$ has a positive contribution to γ . Let $X_0, X_1, X_2, \dots$ and $Y_0, Y_1, Y_2, \dots$ be sets of states sampled from the original and modified chains. Let M and N be stopping times when the original and modified chains first enter either $\mathcal{R}$ or $\mathcal{O}$. The rare-event probability is $\gamma = \Pr\{X_M \in \mathcal{R}\}$.

Standard simulation estimates γ by simulating the original Markov chain to generate multiple samples of $X = I_{\mathcal{R}}(X_M)$. IS simulates the modified Markov chain to generate samples of

$$Y = I_{\mathcal{R}}(Y_N)L(Y_0, Y_1, \dots, Y_N),$$

where the likelihood ratio $L(\cdot)$ of a sample path is

$$L(Y_0, Y_1, \dots, Y_N) = \frac{\prod_{n=1}^N p(Y_{n-1}, Y_n)}{\prod_{n=1}^N p'(Y_{n-1}, Y_n)}. \quad (6)$$

As in the static case, the modified sampling is unbiased: $E[Y] = \gamma$. The main challenge is to find a change of measure so that $\text{Var}[Y] \ll \text{Var}[X]$. As before, it is possible (in theory) to find a change of measure such that $\text{Var}[Y] = 0$. Specifically, the optimal change of measure is

$$p'(x, y) = \frac{\gamma(y)}{\gamma(x)} p(x, y), \quad (7)$$

where $\gamma(x) = \Pr\{X_M \in \mathcal{R} | X_0 = x\}$ is the probability that the original chain enters $\mathcal{R}$ before $\mathcal{O}$, starting in state x . Note that $p'(x, y) = 0$ when $y \in \mathcal{O}$, since $\gamma(y) = 0$ when $y \in \mathcal{O}$. Thus, the optimal change of measure cuts all links to terminating states that are not rare-event states. This forces the chain to eventually hit the rare-event set with probability 1. To verify that $\text{Var}[Y] = 0$

$$\begin{aligned} Y &= I_{\mathcal{R}}(Y_N)L(Y_0, Y_1, \dots, Y_N) \\ &= I_{\mathcal{R}}(Y_N) \frac{\prod_{n=1}^N p(Y_{n-1}, Y_n)}{\prod_{n=1}^N p'(Y_{n-1}, Y_n)} \\ &= I_{\mathcal{R}}(Y_N) \frac{\prod_{n=1}^N p(Y_{n-1}, Y_n) \gamma(Y_{n-1})}{\prod_{n=1}^N p(Y_{n-1}, Y_n) \gamma(Y_n)} \\ &= I_{\mathcal{R}}(Y_N) \frac{\gamma(Y_0)}{\gamma(Y_N)} = \gamma(Y_0). \end{aligned}$$

The last equality follows because $\gamma(Y_N) = I_{\mathcal{R}}(Y_N)$, since Y_N is in a terminating state in either $\mathcal{R}$ or $\mathcal{O}$. Without loss of generality, we can assume that Y_0 is a constant, so $\text{Var}[Y] = \text{Var}[\gamma(Y_0)] = 0$. (If Y_0 is random, define a pseudo-initial state at time -1 that transitions to one of the random initial states at time 0.)

Example. Consider an $M/M/1/K$ queue with arrival rate λ , service rate μ , and maximum system capacity K . The problem is to estimate the probability γ of reaching K customers in the system before returning to the empty state, starting from the empty state. This is equivalent to the gambler's ruin problem in which a gambler makes i.i.d. bets, winning \$1 with probability $p = \lambda/(\lambda + \mu)$ and losing \$1 with probability $q = \mu/(\lambda + \mu)$. The probability $\gamma(n)$ of reaching K in the system before returning to the empty state (or getting K dollars before losing everything), starting with n in the system, has a simple analytic expression [11]

$$\gamma(n) = \frac{1 - (q/p)^n}{1 - (q/p)^K} = \frac{1 - (1/\rho)^n}{1 - (1/\rho)^K}, \quad (8)$$

where $\rho = \lambda/\mu$. Figure 2 shows the transition probabilities of the original chain and a modified chain. From Equation (7), the optimal change of measure is

$$\begin{aligned} p'_n &= \frac{\gamma(n+1)}{\gamma(n)} p = \frac{(1/\rho)^{n+1} - 1}{(1/\rho)^n - 1} p, \\ n &= 1, 2, \dots, K-1. \end{aligned} \quad (9)$$

As $n \rightarrow \infty$, $p'_n \rightarrow (1/\rho)p = q$ (assuming $\rho < 1$). Thus, for large n , the optimal change of measure approximately swaps the arrival and service rates.

Figure 2. $M/M/1/K$ transition probabilities.

Since the optimal change of measure requires the knowledge of the rare-event function $\gamma(\cdot)$, we may wish to consider a restricted set of measures in which the modified transition probabilities are *state independent*, namely, $p'_n \equiv p'$ for some value p' . Intuitively, a larger value for p' makes the rare event more likely, but if it is too large this can be detrimental. To illustrate, suppose that $p' = 1 - \epsilon$, where $\epsilon > 0$ is some small number. The most likely path to $\mathcal{R}$ is a sequence of upward jumps $Y_0 = 1, Y_1 = 2, \dots, Y_{K-1} = K$. This path occurs with probability $(1 - \epsilon)^{K-1} \approx 1$. The likelihood ratio of this path is $[p/(1 - \epsilon)]^{K-1}$. Occasionally, a sample path may backtrack one state before continuing with upward jumps (e.g., $1, 2, 3, 2, 3, 4, \dots, K$). The likelihood ratio of this path is $qp^K/\epsilon(1 - \epsilon)^K$. In other words, the loop from state 3 to 2 to 3 increases the likelihood ratio by the factor $qp/\epsilon(1 - \epsilon)$. This path occurs with probability $\epsilon(1 - \epsilon)^K$; so it contributes the following term to the *second moment* of the likelihood ratio

$$\left(\frac{qp^K}{\epsilon(1 - \epsilon)^K} \right)^2 \epsilon(1 - \epsilon)^K \approx \frac{q^2 p^{2K}}{\epsilon}.$$

This implies that the variance of the overall estimator $Y = I_{\mathcal{R}}(Y_N)L(Y_0, \dots, Y_N)$ can be made arbitrarily large for small enough ϵ . In summary, although $p' = 1 - \epsilon$ has the positive effect of making the rare event very likely ($I_{\mathcal{R}}(Y_N)$ is usually 1), it has the

negative effect of creating the potential for very large likelihood ratios, which acts to increase the variance of the overall estimator $I_{\mathcal{R}}(Y_N)L(Y_0, \dots, Y_N)$.

A better change of measure makes the rare event very likely but also keeps the likelihood ratio roughly constant over these sample paths. This illustrates why switching the arrival and service rates (i.e., $p' = q$ and $q' = p$) is close to optimal. A loop from n to $n - 1$ to n modifies the likelihood ratio by a factor $qp/q'p' = 1$, leaving the likelihood ratio unchanged. The true optimal change of measure in Equation (9) additionally cuts the link to state 0, and also keeps the property that the likelihood ratio remains unchanged over loops (i.e., $qp/q'_n p'_{n-1} = 1$).

The previous one-dimensional examples are relatively simple in that the rare-event probabilities are known and the optimal change of measure can be found exactly. In practical problems, the optimal change of measure is not known and the Markov chains typically have multidimensional states, which increases the difficulty. To some extent, the one-dimensional examples are deceiving because the sample paths that lead to the rare event are readily identified, which is hardly true in higher dimensional settings. We briefly discuss a few approaches for handling more realistic problems. For more detailed summaries of these methods See [4,8].

A first idea is to make heuristic adjustments to push the model toward the rare event. For instance, in the first example, if one were to make an “educated guess” for μ without the aid of Fig. 1, one could probably choose an IS estimator with a smaller variance than standard simulation, but there is no guarantee. If the system is pushed too hard toward the rare event, then the IS estimator may be much worse than standard simulation. In multivariate state spaces, the variety of trajectories that lead to the rare event increases very fast with the dimension and the variance may explode if the densities of those trajectories are not inflated evenly between them. This is hard to achieve without a good understanding of the system behavior.

A more systematic approach, which dates back to the early days of IS in the 1950s, is to approximate the optimal change of measure via an approximation of $\gamma(\cdot)$ by learning it in an adaptive fashion. For example, the state space of the Markov chain can be discretized into a finite number of regions, and the system can be simulated for a period of time to get an initial estimate for $\gamma(\cdot)$ by assuming a simple form (perhaps a constant function) in each region. Then, a change of measure based on Equation (7) can be applied. The system can be simulated again using the new change of measure, and this process can be repeated iteratively. More generally, one can define a parameterized approximation of $\gamma(\cdot)$ with a few parameters and learn a good set of parameter values, for example, by stochastic approximation. These approaches require one to learn and store an approximation of $\gamma(\cdot)$ over the entire state space, and they hit the curse of dimensionality as soon as the dimension of the state space exceeds a few units. They are also impractical when the state space is already discrete but too large.

Asymptotic approximations of $\gamma(\cdot)$ are sometimes readily available in asymptotic regimes where the rare-event probability converges to 0. Plugging these approximations directly into Equation (7) often works nicely when the rare-event probability is very small. For distributions with an exponentially decaying tail, the resulting IS density $g(x)$ is often the original density $f(x)$

multiplied by an exponential factor $e^{\theta x}/K(\theta)$ for some parameter θ , where $K(\theta)$ is a normalizing factor. This is called *exponential twisting* [4,5].

Consider, for example, a sequence of i.i.d. continuous random variables $X_1, X_2, \dots$, with $E[X_i] < 0$ and finite moment generating function around zero so that X_i is light tailed. Define a random walk $\{S_i, i \geq 0\}$ by $S_0 = 0$ and $S_i = S_{i-1} + X_i$. We want to estimate $\gamma = \Pr\{\sup_{i \geq 0} S_i \geq \ell\}$, the probability that the walk ever exceeds a given constant $\ell > 0$, by simulating it as a Markov chain. This model has several applications. For example, it can be used to obtain the steady-state waiting-time distribution of a $GI/G/1$ queue [12, Section 7.2.3]. Large-deviation theory tells us that when γ is small, $\gamma \approx e^{-\theta \ell}$ for some constant θ that depends on the distribution of X_i . Plugging this approximation into Equation (7) (with probabilities replaced by densities) gives an exponentially twisted density that is typically very effective for small γ . The old density $f(x)$ is multiplied by $e^{\theta x}$ for all x and then renormalized.

Another approach to take when the state space is large is to restrict the change of measure to a specific parametric class. Naturally, the parametric class should be chosen so that it includes good measures to begin with. The problem is to estimate the vector of parameters θ that minimizes the variance (or equivalently the second moment $E[\gamma^2]$) within the parametric class. For a given parameter set θ , estimates of $E[\gamma^2]$ are obtained by sample averages from simulation. Minimization of $E[\gamma^2]$ over θ can be conducted using methods from stochastic optimization. A variant of this is the cross-entropy method which, instead of minimizing the variance, minimizes the cross-entropy distance between the selected change of measure and the zero-variance measure [13].

SPLITTING

The idea of splitting is to “split” (or clone) a simulation run into separate runs whenever it gets “near” the rare event of interest (Fig. 3). These runs share a common history up to the splitting point, but conditional on

Figure 3. Level splitting.

that history, they evolve independent of each other. In this way, more computer time is spent on promising runs that are close to the rare event. To make this more concrete, let $X \equiv \{X_t, t \geq 0\}$ be a Markov process (possibly multidimensional) with state space χ . Let $h : \chi \rightarrow \mathbb{R}^+$ be a map of the state space to the “level” of the process; $h(\cdot)$ is sometimes called the *importance function*. Figure 3 shows sample paths of $h(X_t)$. The rare-event set $\mathcal{R}$ is defined as the set of states whose level is at least as large as some constant $l > 0$. In other words, $\mathcal{R} \equiv \{x \in \chi : h(x) \geq l\}$. Let T_R be the time that the process first enters $\mathcal{R}$, and let T_S be the time that the process first returns to level 0. Specifically,

$$T_R \equiv \inf \{t > 0 : h(X_t) \geq l\},$$

$$T_S \equiv \inf \{t > 0 : h(X_t) = 0\},$$

where it is assumed that the process has just left level 0 at time $t = 0$ ($h(X_0) > 0$ and $h(X_{0-}) = 0$). The probability to estimate is $\gamma \equiv \Pr\{T_R < T_S\}$. For example, if $h(X_t)$ denotes the number of customers in a queueing system at time t , then $\{T_R < T_S\}$ is the event that the number in the system reaches some critical threshold (say, a buffer overflow) before the system empties.

To implement level splitting, define a sequence of m levels $0 < l_1 < \dots < l_m$, where $l_m \equiv l$. Let $T_j \equiv \inf\{t > 0 : h(X_t) \geq l_j\}$ be the time that the process first crosses l_j ($j = 1, \dots, m$). Let $D_j \equiv \{T_j < T_S\}$ be the event that the process crosses l_j before returning to 0 ($j = 1, \dots, m$). Let $p_j \equiv \Pr\{D_j | D_{j-1}\}$ be the probability that the process crosses

l_j (before returning to 0), given that the process has crossed l_{j-1} (before returning to 0) ($j = 2, \dots, m$). Also, let $p_1 \equiv \Pr\{D_1\}$. Since $D_m \subset D_{m-1} \subset \dots \subset D_1$,

$$\gamma = \Pr\{D_m\} = \Pr\{D_1\}\Pr\{D_2|D_1\}$$

$$\dots \Pr\{D_m|D_{m-1}\} = p_1 p_2 \dots p_m.$$

The basic idea is to estimate each p_j separately, rather than to estimate γ on its own. There are many variations of level splitting, and we describe some of the key ideas here.

Fixed Splitting

In this approach, any simulation run that reaches a new level is split into a fixed number R of independent runs. (The splitting factor can also be generalized so that it is level dependent, R_i .) For example, in Fig. 3, the splitting factor is $R = 3$. A run that down-crosses and up-crosses a level is only split at the first up-crossing. Each run that reaches the rare event comes from a sequence of m splits, each by a factor R . Thus, each hit to the rare event is weighted by the factor $1/R^m$ to produce an unbiased estimator.

An advantage of fixed splitting is that it can be implemented recursively in a depth-first manner. This means that the computer only needs to store, at most, a single system state per level, corresponding to the simulation history of the current run. To implement fixed splitting, the simulation starts at an initial state and proceeds until it reaches either level 1 or level 0. If level 0 is reached, the replication terminates; if level 1 is reached,

the simulation is split into R clones. The first clone is simulated until it reaches either level 2 or level 0. If level 0 is reached, the clone terminates, and the next clone at level 1 is simulated; if level 2 is reached, the simulation is split again, and so forth. This process continues so that all offsprings of a clone are simulated to conclusion before proceeding to the next clone.

One drawback with fixed splitting is that it is sensitive to the choice of the splitting factor R . If R is too high, the total number of runs and the amount of work explode. If R is too low, then few simulations reach the rare event.

Fixed-Effort Splitting

In this approach, a predetermined total number of runs n_i are made at each level. This is different from fixed splitting where the *total* number of runs at each level is random based on the outcomes of runs at lower levels. The main advantage is that there is no need to know a good splitting factor R in advance, and because the total number of runs at each level is fixed, the overall variance is often lower. The drawback is that the computer must store all of the entrance states to a level to serve as the candidate starting states for simulation of the next level. This can lead to memory problems for models with large state spaces.

One way to implement fixed-effort splitting is the following: conduct n_1 runs starting from the initial state and simulate each until the system reaches level 1 or returns to level 0. The end states of the runs that reach level 1 are collected into a set A_1 . These states become the starting states for the next stage of simulation. (A_1 may include duplicate copies of the same state.) Simulation at stage 2 draws n_2 starting states at random, with replacement, from the set A_1 and simulates each run until the system reaches level 2 or returns to level 0. The method proceeds in an analogous manner at higher stages. After that, an unbiased estimator for the rare-event probability is $\hat{\gamma} \equiv \hat{p}_1 \hat{p}_2 \dots \hat{p}_m$, where $\hat{p}_i$ is the number of runs that reach level i divided by n_i .

Fixed-Success Splitting and Fixed Probability of Success

In *fixed-success splitting* [14], at each level, the total number of trajectories that must reach the next level is fixed; independent replications at the current level continue until the fixed number of successes is achieved. According to Amrein and Künsch [15], this approach is often superior to fixed-splitting and fixed-effort approaches. In *fixed probability of success*, the levels are learned adaptively so that the probability of reaching the next level is approximately the same at all levels.

By far the most difficult issue in splitting, when the state space has more than one dimension, is the choice of the importance function $h(\cdot)$. In one dimension, the choice is typically straightforward. For example, for an $M/M/1$ queue, a natural choice is $h(x) = x$, where x is the number of customers in the system. In fact, all increasing functions in x are equivalent, provided one is free to select the location of the levels. The problem becomes more complicated when the state space is multidimensional. To illustrate, consider a two-stage Markovian tandem queue example, taken from Glasserman *et al.* [16]. Let (x_1, x_2) represent the numbers of customers at each station, and let γ be the probability of a buffer overflow at the *second* queue (prior to returning to an empty system). An intuitive choice for the level function is $h(x_1, x_2) = x_2$, since $\mathcal{R}$ is defined purely in terms of x_2 . This turns out to be a bad choice when the first queue is a bottleneck. The reason is that h does not adequately capture *how* the system gets to the rare event. The system typically gets to $\mathcal{R}$ by building up customers at the first queue and then transferring them to the second queue. Thus, a system in state $(x_1 = \text{large}, x_2 = \text{small})$ is “close” to the rare event even though $h(x_1, x_2) = x_2$ is small indicating that the system is far away from $\mathcal{R}$. Thus, h does not adequately favor sample paths that are likely to reach the rare event. A better choice is $h(x_1, x_2) = [x_2 + \min(0, x_2 + x_1 - l)]/2$, where l is the overflow level of the second queue [14,17]. Intuitively, this function is proportional to the minimal number of steps to the rare event (arrivals to the first queue and

transfers to the second queue). In summary, a good choice for the importance function is not necessarily obvious, and a poor choice can increase the variance over crude Monte Carlo. The same type of difficulty occurs when IS is applied to multidimensional systems: the change of measure must favor the sample paths that are representative of how the model reaches the rare event; otherwise the variance can blow up.

One practical issue in splitting is that it can take a long time to simulate from a high level down to level 0. This is inefficient, since a lot of time is spent simulating descending runs that are not likely to rise back up to hit higher levels. The idea of *truncation* is to terminate runs that sink below some threshold under the assumption that they will eventually sink to 0. This reduces computation time but introduces a bias. *Probabilistic truncation* implements this idea in an unbiased way: consider a run that starts at level k and down-crosses level $k - j$, where $j \geq 1$. The run continues with probability $1/r_{kj}$ and is terminated with probability $1 - 1/r_{kj}$, where $r_{kj} \geq 1$ are pre-chosen constants. A run that continues has its weights multiplied by r_{kj} to eliminate the bias. The general idea of killing some trajectories with some probability and inflating their weight when they survive is called *Russian roulette* in the Monte Carlo literature. Other variations include periodic truncation and tag-based truncation. A well-known variant of splitting that incorporates truncation is the RESTART method [18].

To see the kinds of improvements that are possible with splitting, consider a problem in which the levels are chosen so that the probabilities p_i are equal, namely, $p_i = \gamma^{1/m}$. For example, in the $M/M/1/K$ model, choosing evenly spaced levels l_i (e.g., $l_i = ki$ for some constant $k > 0$) yields approximately equal values for p_i (at least for large i). Under a fixed-effort implementation with $n_i \equiv n$ and $p_i = \gamma^{1/m}$, it is relatively straightforward to show [7] that splitting reduces $\text{Var}[\hat{\gamma}]$ by a factor $m^2 \gamma^{1-1/m}$ compared with standard simulation. Taking the derivative with respect to m shows that $m \approx -(\ln \gamma)/2$ achieves the best improvement. For example, if $\gamma = 10^{-9}$, then it is roughly optimal to select $m = 10$ levels yielding a variance

reduction of approximately six orders of magnitude. However, it is not always easy to choose levels so that the p_i are equal. One adaptive approach is to conduct an initial set of simulations to approximate the appropriate levels [6, Section 3.3]. Also, this analysis implicitly ignores the actual time to simulate each level. In practice, it typically takes longer to simulate runs that start at higher levels. This reduces the variance reduction achieved for a fixed computing budget.

Splitting can also be applied without pre-defining any levels for the importance function. A splitting or Russian roulette decision can be made at any step of the chain depending on its current weight and current value of the importance function [7]. Finally, particle filters and sequential Monte Carlo methods, popular in computational statistics, are closely related to fixed-effort splitting; see Andrieu *et al.* [19] and the references given therein.

OPTIMIZATION UNDER UNCERTAINTY

Mathematical programming models involving uncertain parameters were introduced as early as 1955, with Dantzig's work on linear programming under uncertainty [1]. To illustrate the various approaches for dealing with uncertainty in optimization, we first introduce a generic deterministic optimization problem

$$\min f(\mathbf{x}, \xi) \quad \text{s.t. } \mathbf{x} \in X(\xi), \quad (1)$$

where $\xi \in \mathbb{R}^d$ is a data vector, $\mathbf{x}$ is the decision vector, and where $X(\xi) \subseteq \mathbb{R}^n$ and $f(\cdot, \xi) : \mathbb{R}^n \mapsto \mathbb{R}$ are the feasible region (defined by constraints) and the objective function, respectively, corresponding to the data vector ξ . The goal is to select a decision $\mathbf{x}$ from the feasible set of decisions $X(\xi)$ such that the objective function $f(\mathbf{x}, \xi)$ is minimized. If the data ξ defining f and X are deterministic and completely observable by the decision maker in advance of the optimization process, then one turns to a suite of algorithms dedicated to solving such problems. In most practical settings, however, this assumption does not hold. For instance, it may be impossible to specify future prices, for example, as in the case of portfolio investments [2,3]. Errors may also arise due to numerical instability or measurement inaccuracies [4]. Furthermore, even if exact data has been provided to the decision maker, the implementation

of a continuous-valued solution that involves several digits of precision may be impossible (e.g., as in Ref. 5).

To properly address Equation (1) in the presence of uncertainty on ξ , we need an appropriate model of uncertainty of ξ . There are three common paradigms: (i) In the stochastic programming paradigm, the uncertain parameter ξ is modeled as a random variable ξ with a known distribution. Thus, for a given solution $\mathbf{x}$, feasibility $\mathbf{x} \in X(\xi)$ is a random event and the objective function $f(\mathbf{x}, \xi)$ is a random variable, and stochastic programming models seek a solution $\mathbf{x}$ that is feasible with sufficiently high probability and minimizes some statistic, say expectation, of the random objective. (ii) In contrast, the robust optimization paradigm models the uncertainty in ξ via an uncertainty set $\mathcal{U}$, and seeks a solution $\mathbf{x}$ that is feasible for all possible realizations of $\xi \in \mathcal{U}$ and minimizes the worst-case objective $\max_{\xi \in \mathcal{U}} \{f(\mathbf{x}, \xi)\}$. (iii) A middle ground between the previous two extremes are stochastic programs with partial distributional information. In this setting, a family of distributions on the uncertain parameter ξ is assumed, and a solution that is feasible with high probability and minimizes some statistic over the worst-case distribution from the family is sought. In this article we restrict our focus to paradigm (ii). At first glance, the robust optimization framework may appear overly pessimistic. However, the conservativeness of the approach can be controlled by appropriately constructing the uncertainty set. Much of the research in this area is on constructing appropriate uncertainty sets that

- properly capture the underlying uncertainty and the decision maker's aversion to it; and
- lead to tractable optimization models.

There is a huge body of literature on a variety of robust optimization models. Here, we describe some of the simplest ones for

the case of linear optimization. This article begins in the section titled “Robust Linear Programming Setup” by introducing foundational concepts related to robust linear optimization. In the section titled “Solving Robust LPs”, we discuss robust linear programming optimization fundamentals. We conclude in the section titled “Extensions” with a brief discussion of some extensions to robust linear optimization. This article is meant to be self-contained; however, we refer readers to the foundational works of modern robust optimization theory, pioneered independently by Ben-Tal and Nemirovski [2,4,6,7] and by El-Ghaoui with Lebreton [8] (and with Oustry and Lebreton [9]). A thorough treatment of robust optimization is available in the book [10] and a tutorial treatment is provided in Ref. 11.

ROBUST LINEAR PROGRAMMING SETUP

We consider the case of a linear programming problem, where A is an $m \times n$ matrix:

$$\min \mathbf{c}'\mathbf{x} \quad (2a)$$

$$\text{s.t. } A\mathbf{x} \geq \mathbf{b} \quad (2b)$$

$$\mathbf{l} \leq \mathbf{x} \leq \mathbf{u}, \quad (2c)$$

where $\mathbf{c}$ and $\mathbf{b}$ have conforming dimensions, and where the problem data values $(\mathbf{c}, A, \mathbf{b})$ are unknown. In fact, we can restrict ourselves without loss of generality to problems in which only the constraint coefficient data A is uncertain, by rewriting the problem above as

$$\min t \quad (3a)$$

$$\text{s.t. } t - \mathbf{c}'\mathbf{x} \geq 0, \quad (3b)$$

$$A\mathbf{x} - \mathbf{b}w \geq 0, \quad (3c)$$

$$\mathbf{l} \leq \mathbf{x} \leq \mathbf{u}, w = 1. \quad (3d)$$

Note in Equation (3) that the uncertainty appears only in the constraint coefficient data.

Now, suppose that A belongs to the uncertainty set $\mathcal{U}$, and that all other data is treated as certain. The *robust counterpart* of Equation (2) replaces Equation (2b) with

$$\bar{A}\mathbf{x} \geq \mathbf{b} \quad \forall \bar{A} \in \mathcal{U}.$$

As a result, we have a *semi-infinite program*; that is, a mathematical program with a finite number of decision variables but with an infinite number of constraints.

As an illustration, consider the problem

$$\min x_1 + x_2, \quad (4a)$$

$$\text{s.t. } (4 - \Delta_{11})x_1 + (1 - \Delta_{12})x_2 \geq 4, \quad (4b)$$

$$(1 - \Delta_{21})x_1 + 5x_2 \geq 10, \quad (4c)$$

$$-x_1 + x_2 \geq 5, \quad (4d)$$

$$x_1, x_2 \geq 0, \quad (4e)$$

and suppose that $\mathcal{U}$ is the following polytope:

$$\mathcal{U} = \{\Delta_{11}, \Delta_{12}, \Delta_{21} \geq 0 : \Delta_{11} + \Delta_{12} + \Delta_{21} \leq 1\}.$$

When all Δ -values equal zero, we have a nominal feasible region as depicted in Fig. 1. Looking at convex combinations of the points $(\Delta_{11}, \Delta_{12}, \Delta_{21}) = (1, 0, 0)$ and $(0, 1, 0)$, we generate the infinite collection of constraints corresponding to these values as depicted in Fig. 2. Note that Equation (4b) holds for each $\Delta \in \mathcal{U}$ if and only if

$$4x_1 + x_2 + \min_{\Delta \in \mathcal{U}} (-\Delta_{11}x_1 - \Delta_{12}x_2) \geq 4.$$

Figure 1. Feasible region for problem (4) in which $\Delta_{11} = \Delta_{12} = \Delta_{21} = 0$.

Figure 2. Generation of robust constraints with respect to Equation (4b). The dotted constraint corresponds to the case in which $\Delta_{11} = \Delta_{12} = 0$.

Figure 3. Generation of robust constraints with respect to Equation (4c). The dotted constraint corresponds to the case in which $\Delta_{21} = 0$.

Because $\min_{\Delta \in \mathcal{U}} (-\Delta_{11}x_1 - \Delta_{12}x_2) = \min\{-x_1, -x_2\}$, the robust version of Equation (4b) can be written as the system of two constraints $3x_1 + x_2 \geq 4$ and $4x_1 \geq 4$. Similarly, note that as we consider convex combinations of points between $(\Delta_{11}, \Delta_{12}, \Delta_{21}) = (0, 0, 0)$ and $(0, 0, 1)$, an infinite number of constraints are generated as shown in Fig. 3, all of which are dominated by the constraint

$5x_2 \geq 10$. The robust counterpart in this case replaces Equation (4b) with two constraints $3x_1 + x_2 \geq 4$ and $4x_1 \geq 4$, and replaces Equation (4c) with $5x_2 \geq 10$.

The key technique to solving the semi-infinite robust counterpart is to exploit the structure of $\mathcal{U}$ and reformulate the problem as a finite-dimensional optimization problem (perhaps in higher dimension) so as to make it amenable to standard (deterministic) mathematical programming tools. Before proceeding to discuss these reformulations, we examine several properties that are vital to understanding these problems.

Column-Wise Uncertainty. Suppose that we let $\mathbf{a}_j$ denote the j th column of A , for $j = 1, \dots, n$. Now, suppose that uncertainty in A is column-wise, in the sense that uncertainty in $\mathbf{a}_i$ and $\mathbf{a}_j$ are independent, for each $1 \leq i < j \leq n$. Thus, we write $\mathbf{a}_j \in \mathcal{U}_j$, and $\mathcal{U} = \mathcal{U}_1 \times \dots \times \mathcal{U}_n$. This case is considered in one of the earliest studies on robust optimization by Soyster [12].

Consider any constraint i and, for the sake of simplicity, suppose that $\mathbf{x} \geq 0$. This constraint can be written as

$$a_{i1}x_1 + a_{i2}x_2 + \dots + a_{in}x_n \geq b_i.$$

Note that because uncertainty is column-wise, variations in $a_{i1}, a_{i2}, \dots, a_{in}$ are independently determined [12]. We can therefore optimize *a priori* to determine $\underline{a}_{ij} = \inf\{\hat{a}_{ij} : \mathbf{a}_j \in \mathcal{U}_j, \hat{a}_{ij} = \hat{a}_{ij}\}$. This gives rise to a simple characterization of the problem's robust counterpart:

$$\underline{A}\mathbf{x} \geq \mathbf{b}, \mathbf{x} \geq 0,$$

where $\underline{A}$ is the matrix of entries $\underline{a}_{ij}$.

Equivalence with Row-Wise Uncertainty. Now, let $\mathbf{a}^i$ denote the i th row vector of A , and define $\mathcal{U}_i = \{\mathbf{a}^i : \exists A \in \mathcal{U} \text{ with row } i \text{ of } A = \mathbf{a}^i\}$. One can think of this as the projection of $\mathcal{U}$ onto the set of all possible combinations of constraint i coefficients. Observe that in the robust counterpart, $\mathbf{x}$ must be feasible for *any* $A \in \mathcal{U}$. Therefore, $\mathbf{x}$ is feasible if and only if:

$$(\mathbf{a}^i)' \mathbf{x} \geq b_i \quad \forall \mathbf{a}^i \in \mathcal{U}_i \quad \forall i = 1, \dots, m.$$

The implication is therefore that we can assume row-wise uncertainty of the constraint matrix, in which the distribution of the constraint coefficients are row-wise independent. That is, optimizing over the uncertainty set in which $A \in \mathcal{U}$ is equivalent to optimizing over the uncertainty set in which A belongs to the (larger) set $\mathcal{U}_1 \times \dots \times \mathcal{U}_m$.

Indeed, one can see this from the prior example given in Figs 1–3, in which uncertainty was considered separately for constraints (4b) and (4c). Define $\mathcal{U}_1 = \{\Delta_{11}, \Delta_{12} \geq 0 : \Delta_{11} + \Delta_{12} \leq 1\}$ and $\mathcal{U}_2 = \{\Delta_{21} : 0 \leq \Delta_{21} \leq 1\}$. Then optimizing over $\bar{\mathcal{U}} = \mathcal{U}_1 \times \mathcal{U}_2$ is equivalent to optimizing over $\mathcal{U}$ (even though $\bar{\mathcal{U}} \supset \mathcal{U}$).

Convexity and Closedness of Uncertainty Set. First, note that if $\mathbf{x}$ is feasible with respect to $A^1 \in \mathcal{U}$ and $A^2 \in \mathcal{U}$, then it is also feasible with respect to constraint matrix $\lambda A^1 + (1 - \lambda)A^2$, for $0 \leq \lambda \leq 1$. Therefore, optimizing over uncertainty set $\mathcal{U}$ and over its convex hull are equivalent. Furthermore, optimizing over the closure of $\mathcal{U}$ is equivalent to optimizing over $\mathcal{U}$. Therefore, we can assume that, for robust linear programming problems, the uncertainty set is row-wise uncertain, closed, and convex [5].

SOLVING ROBUST LPs

As mentioned before, the key approach in solving semi-infinite robust optimization problems is to reformulate them as standard mathematical programs by exploiting the structure of the uncertainty set $\mathcal{U}$. In this section, we focus on problems of the form of Equation (2), in which the A -values are uncertain. The standard approach that we take here is to handle robustness by envisioning the problem as a Stackelberg (leader–follower) game: The leader chooses a candidate value $\mathbf{x}$, and the follower attempts to choose an A -matrix in the set $\mathcal{U}$ to make $\mathbf{x}$ infeasible. This type of game is often handled in mathematical programming by dualizing the follower's problem, which allows the leader/follower problem to be combined and solved as a single optimization problem. However, in this setting, the follower's

problem is often easily solvable as we will see below.

In the rest of this section, we consider four types of uncertainty sets, and briefly describe the reformulation of the corresponding robust counterparts into standard mathematical programs.

Interval Uncertainty

In this model, each element a_{ij} of the A matrix ($i = 1, \dots, m$, $j = 1, \dots, n$) is uncertain but belongs to some interval $[\bar{a}_{ij} - \hat{a}_{ij}, \bar{a}_{ij} + \hat{a}_{ij}]$ for all j . Given a value of $\mathbf{x}$, the worst-case scenario is that $a_{ij} = \bar{a}_{ij} - \hat{a}_{ij}$ if $x_j > 0$, and $a_{ij} = \bar{a}_{ij} + \hat{a}_{ij}$ otherwise. (In the context of the Stackelberg game above, the follower chooses a value of a_{ij} within the allowable interval that minimizes $a_{ij}x_j$, noting that the constraints are of the $\geq$ sense.) Letting $\bar{A}$ ($\hat{A}$) be the collection of $\bar{a}_{ij}$ -values ($\hat{a}_{ij}$ -values), we get the following robust counterpart formulation

$$\begin{aligned} \min \quad & \mathbf{c}'\mathbf{x}, \\ \text{s.t.} \quad & \bar{A}\mathbf{x} - \hat{A}|\mathbf{x}| \geq \mathbf{b}, \\ & \mathbf{l} \leq \mathbf{x} \leq \mathbf{u}. \end{aligned}$$

Linearizing $|\mathbf{x}|$ can be done in a number of ways. Here, we define variables $y_j = |x_j|$ for $j = 1, \dots, n$, and enforce constraints $-\mathbf{y} \leq \mathbf{x} \leq \mathbf{y}$. (Since an optimal solution exists in which the y -variables take on their smallest possible values given x , these constraints are sufficient to force $y_j = |x_j|$ at optimality.) We then obtain the following linear program:

$$\min \quad \mathbf{c}'\mathbf{x}, \tag{5a}$$

$$\text{s.t.} \quad \bar{A}\mathbf{x} - \hat{A}\mathbf{y} \geq \mathbf{b}, \tag{5b}$$

$$-\mathbf{y} \leq \mathbf{x} \leq \mathbf{y}, \tag{5c}$$

$$\mathbf{l} \leq \mathbf{x} \leq \mathbf{u}. \tag{5d}$$

Note here that this is a special case of column-wise uncertainty. If $\mathbf{l} \geq 0$, then no y -variables are required in the formulation: we can remove Equation (5c) and replace Equation (5b) with

$$(\bar{A} - \hat{A})\mathbf{x} \geq \mathbf{b}.$$

It is also important to observe that the uncertainty set $\mathcal{U}$ is polyhedral, and that the robust counterpart to the original problem remains a linear program. We will see that this result holds true in the next two sections as well, which involve more sophisticated types of polyhedral uncertainty.

Budgeted Uncertainty

The case of *budgeted uncertainty* is studied by Bertsimas and Sim [3], and requires slightly more analysis than the interval uncertainty case. We begin by describing the uncertainty set. Let $\Gamma_i \leq n$ be a given integer for all i . Each coefficient a_{ij} of the i -th constraint belongs to an interval $[\bar{a}_{ij} - \hat{a}_{ij}, \bar{a}_{ij} + \hat{a}_{ij}]$, and no more than Γ_i of the coefficients $a_{i1}, \dots, a_{in}$ are allowed to vary simultaneously. Bertsimas and Sim [3] show that such an uncertainty set can be written as

$$a_{ij} = \bar{a}_{ij} + z_{ij}\hat{a}_{ij}, \quad (6)$$

with

$$0 \leq |z| \leq 1 \text{ and } \sum_j |z_{ij}| \leq \Gamma_i \quad \forall i = 1, \dots, m. \quad (7)$$

The “follower” in the Stackelberg analogy chooses, for each row, a set of coefficients that may deviate from their nominal values of $\bar{a}_{ij}$. In the interval uncertainty case, the follower chooses all n coefficients for each constraint, where by contrast, only a “budget” of Γ_i such coefficients can be changed in the budgeted uncertainty case.

The underlying rationale behind this budgeting (and indeed, behind most commonly used uncertainty sets) is that it is unlikely that all data will simultaneously take on their worst possible values (i.e., those values that most tightly constrain the feasible region), even if the “true” uncertainty set is the interval uncertainty set in the section titled “Interval Uncertainty.” Thus, if one considers the case in which only Γ_i out of n values for constraint i take on their worst possible values (assuming that Γ_j and z are integer-valued), then one introduces a slight risk of obtaining an infeasible solution when

the actual data is revealed (when $\Gamma_i < n$), but potentially improves the objective function value of the solution as the problem becomes less-constrained. Indeed, smaller values of Γ_i will cause the optimal objective function value to stay the same or decrease, but will increase the chances that the resulting solution will be infeasible.

In this case, given $\mathbf{x}$, we must account for the fact that the left-hand side is as small as

$$\sum_{j=1}^n \bar{a}_{ij}x_j - \sum_{j=1}^n \hat{a}_{ij}|x_j|z_{ij} \quad \forall i = 1, \dots, m. \quad (8)$$

Hence, the follower in a Stackelberg game—trying to force $\mathbf{x}$ to be infeasible—would solve the following optimization problem.

$$\max \sum_{j=1}^n \hat{a}_{ij}|x_j|z_{ij}, \quad (9a)$$

$$\text{s.t. } \sum_{j=1}^n z_{ij} \leq \Gamma_i, \quad (9b)$$

$$0 \leq z_{ij} \leq 1 \quad \forall j = 1, \dots, n. \quad (9c)$$

Associating dual variable π_i with Equation (9b) and μ_{ij} , $j = 1, \dots, n$, with the upper bounding constraints in Equation (9c), we obtain the following (linear programming) dual formulation of Equation (9):

$$\min \Gamma_i \pi_i + \sum_{j=1}^n \mu_{ij}; \quad (10a)$$

$$\text{s.t. } \pi_i + \mu_{ij} \geq \hat{a}_{ij}|x_j| \quad \forall j = 1, \dots, n; \quad (10b)$$

$$\pi_i \geq 0, \mu_{ij} \geq 0 \quad \forall j = 1, \dots, n. \quad (10c)$$

Therefore, we can replace the term $\sum_{j=1}^n \hat{a}_{ij}|x_j|z_{ij}$ in Equation (8) with the objective function term $\Gamma_i \pi_i + \sum_{j=1}^n \mu_{ij}$ in (10a), constrained by Equation (10b) and Equation (10c). Furthermore, replacing $y_j = |x_j|$ using the same substitution strategy as in the section titled “Interval Uncertainty,” we obtain the following robust counterpart.

$$\begin{aligned}
& \min \quad \mathbf{c}'\mathbf{x}; \\
& \text{s.t.} \quad \bar{\mathbf{a}}^i \mathbf{x} - \left(\Gamma_i \pi_i + \sum_{j=1}^n \mu_{ij} \right) \geq b_i \\
& \quad \quad \quad \forall i = 1, \dots, m; \\
& \quad \quad \quad \pi_i + \mu_{ij} \geq \hat{a}_{ij} y_j \quad \forall j = 1, \dots, n; \\
& \quad \quad \quad -y_j \leq x_j \leq y_j \quad \forall j = 1, \dots, n; \\
& \quad \quad \quad \pi, \mu \geq 0; \\
& \quad \quad \quad \mathbf{l} \leq \mathbf{x} \leq \mathbf{u}.
\end{aligned}$$

Observe that the robust counterpart simultaneously computes both an optimal robust solution $\mathbf{x}$, and a worst-case set of parameter values while preserving the linear structure of the problem.

A vital question addressed by Bertsimas and Sim [3] regards the probability that constraint i is violated, given budgeted uncertainty Γ_i . Assume that in reality, $a_{ij} \in [\bar{a}_{ij} - \hat{a}_{ij}, \bar{a}_{ij} + \hat{a}_{ij}]$ for each i and j . Furthermore, assume that the distribution of a_{ij} is symmetric over this interval. Then Bertsimas and Sim [3] show that the probability of violating constraint i is approximately no more than

$$1 - \Phi\left(\frac{\Gamma_i - 1}{\sqrt{n}}\right),$$

where Φ is the cumulative distribution function of a standard normal random variable.

Polyhedral Uncertainty

The previous sections beg the question of whether or not one can still obtain a robust counterpart to the original linear program if the uncertainty set is a general polyhedron. We answer this question in the affirmative in this section. Our uncertainty set in this case is Equation (6) with the z -variables constrained as follows for each $i = 1, \dots, m$:

$$F_i |\mathbf{z}_i| \leq \mathbf{g}_i \quad \text{and} \quad |z_{ij}| \leq 1 \quad \forall j = 1, \dots, n, \quad (11)$$

where $F_i \in \mathbb{R}^{k_i \times n}$ and $\mathbf{g}_i \in \mathbb{R}^{k_i \times 1}$. In this case, we wish to optimize Equation (9a) subject to constraints (11). This problem can be

converted to an equivalent linear program by shifting the absolute values from the z -variables to the x -variables as follows:

$$\max \quad \sum_{j=1}^n \hat{a}_{ij} |x_j| z_{ij}, \quad (12a)$$

$$\text{s.t.} \quad F_i \mathbf{z}_i \leq \mathbf{g}_i, \quad (12b)$$

$$z_{ij} \leq 1 \quad \forall j = 1, \dots, n. \quad (12c)$$

The dual of Equation (12) is given by the following:

$$\begin{aligned}
& \min \quad \mathbf{g}'_i \pi_i + \sum_{j=1}^n \mu_{ij}, \\
& \text{s.t.} \quad F'_i \pi_i + \mu_i \geq \text{diag}(\hat{\mathbf{a}}^i) |\mathbf{x}|, \\
& \quad \quad \pi_i, \mu_i \geq 0.
\end{aligned}$$

Substituting $\sum_{j=1}^n \hat{a}_{ij} |x_j| z_{ij}$ with optimization problem (12) and linearizing the absolute value terms, we get the following (linear programming) robust counterpart.

$$\begin{aligned}
& \min \quad \mathbf{c}'\mathbf{x}; \\
& \text{s.t.} \quad \bar{\mathbf{a}}^i \mathbf{x} - \left(\mathbf{g}'_i \pi_i + \sum_{j=1}^n \mu_{ij} \right) \geq b_i \\
& \quad \quad \quad \forall i = 1, \dots, m; \\
& \quad \quad \quad F'_i \pi_i + \mu_i \geq \text{diag}(\hat{\mathbf{a}}^i) \mathbf{y} \quad \forall i = 1, \dots, m; \\
& \quad \quad \quad -y_j \leq x_j \leq y_j \quad \forall j = 1, \dots, n; \\
& \quad \quad \quad \pi, \mu \geq 0; \\
& \quad \quad \quad \mathbf{l} \leq \mathbf{x} \leq \mathbf{u}.
\end{aligned}$$

Ellipsoidal Uncertainty

The robust optimization approach taken by Ben-Tal and Nemirovski [4] examine ellipsoidal uncertainty sets $\mathcal{U}_i$, for $i = 1, \dots, m$. For simplicity (and without loss of generality after scaling), we can consider hypersphere sets (that no longer contain “box constraints” of the form $|z_{ij}| \leq 1$):

$$\mathcal{U}_i = \{\mathbf{z}_i : \|\mathbf{z}_i\|_2 \leq \Omega_i\}. \quad (13)$$

For each constraint $i = 1, \dots, m$, we guarantee that $\mathbf{x}$ is feasible over the uncertainty set by maximizing $\sum_{j=1}^n \hat{a}_{ij}x_jz_{ij}$ over the z -variables, subject to Equation (13). Thus, one would maximize in the direction $(\hat{\mathbf{a}}_i)'\mathbf{x}$ over Equation (13), and the optimal objective function value is given by

$$\Omega_i \sqrt{\sum_{j=1}^n (\hat{a}_{ij}x_j)^2}. \quad (14)$$

Substituting $(\hat{\mathbf{a}}_i)'\mathbf{x}$ with (14), we obtain the following (nonlinear) second-order cone program:

$$\min \quad \mathbf{c}'\mathbf{x}; \quad (15a)$$

$$\begin{aligned} \text{s.t.} \quad & \bar{\mathbf{a}}^i\mathbf{x} - \Omega_i \sqrt{\sum_{j=1}^n (\hat{a}_{ij}x_j)^2} \geq b_i \\ & \forall i = 1, \dots, m; \end{aligned} \quad (15b)$$

$$\mathbf{l} \leq \mathbf{x} \leq \mathbf{u}. \quad (15c)$$

Observe that unlike in the case of robust linear programming with budgeted uncertainty, model (15) does not require any auxiliary variables. Ben-Tal and Nemirovski [4] show that the probability of violating constraint i , using the ellipsoidal uncertainty set model, assuming that a_{ij} is symmetrically distributed over the interval $[\bar{a}_{ij} - \hat{a}_{ij}, \bar{a}_{ij} + \hat{a}_{ij}]$, is $\exp(-\Omega_i^2/2)$.

Note that the robust counterpart (Eq. 15) is nonlinear due to the fact that the uncertainty sets are ellipsoidal rather than polyhedral. Furthermore, Ben-Tal and Nemirovski [13] demonstrate a similar behavior in conic uncertainty sets (which generalize all of the uncertainty sets described thus far), and show how more complex uncertainty sets accordingly induce more complex robust counterpart formulations.

EXTENSIONS

To conclude this article, we briefly discuss ongoing research areas in the field of robust optimization.

In the section titled “Solving Robust LPs,” we see that linear programming problems remain linear under their robust counterpart if the uncertainty sets are polyhedral. One may therefore postulate that polynomially solvable mixed-integer programming problems, such as shortest path or assignment problems, remain polynomially solvable given polyhedral uncertainty sets. However, Kouvelis and Yu [14] show that this conjecture is not true. Even under *scenario uncertainty* (in which there are a finite number of possible realizations for stochastic data) with just two scenarios, and uncertainty restricted to the objective function coefficients, the robust shortest path problem can be NP-hard. (Consider two possible sets of cost coefficients, with an objective to minimize the maximum of the two possible objective function values. This problem is isomorphic to the resource-constrained shortest path problem, which is NP-hard.)

Therefore, there is a need to study robust discrete optimization problems using a different set of analytical tools. One approach, taken by Bertsimas and Sim [15], is to identify certain polynomially solvable robust discrete optimization problems. In particular, they provide a polynomial-time algorithm for solving combinatorial optimization problems when uncertainty is limited to the objective function coefficients, uncertainty sets are modeled using the uncertainty budget as described in the section titled “Budgeted Uncertainty,” and the nominal (nonrobust) optimization problem itself is polynomially solvable. Another approach seeks stronger problem formulations and classes of valid inequalities that can be used to improve the solvability of robust counterpart formulation. One such notable approach for NP-hard robust counterparts is given by Atamtürk [16].

Next, the concept of *adjustability* or *recourse* is foundational in stochastic programming, but is an emerging area of robust optimization. After a set of decisions is made before values of the uncertain data is realized, a set of recourse decisions allow a second, reactionary set of decisions to be made after the realization of uncertain

data. Atamtürk and Zhang [17] examine robust network flow problems with recourse. Their paper involves a situation in which initial flows are sent across the network before demands are realized and then, the remaining flows are transmitted after the realization of demands. They extend their results to problems involving discrete decisions on capacity allocation (and thus network design) decisions. Bertsimas and Thiele [18] examine robust multistage inventory optimization problems (see also their tutorial article [11]).

Finally, research in this field is still young, and many more advanced issues pertaining to robust optimization have recently been explored [19–23]. We recommend an on-line resource at <http://www.robustopt.com>, which contains a current bibliography of robust optimization literature, along with Matlab software tools designed to automatically formulate robust counterparts such as those mentioned in this article.

INTRODUCTION

A shop floor can be defined as all the production and human resources needed to produce semifinished or finished physical goods. A shop floor is usually organized according to the complexity of the product flow and the flexibility of the resources. For instance, for high variety manufacturing, the shop floor may be organized in job shops when product flows are arbitrary and resources are flexible. In contrast, for high volume manufacturing, a shop floor may be organized as a flow shop or an assembly transfer line. The main objective of a shop-floor control (SFC) system is to keep production execution as close as possible to its plan by taking appropriate corrective actions. In order to meet this objective, SFC system need to measure current execution and compare this feedback with the plan to detect any deviations from the plan as illustrated in Fig. 1.

Some of the main attributes of SFC include

- short-time horizons (e.g., minutes) in comparison with planning (e.g., days or weeks);
- the need to compensate for disturbances and modeling errors in the planning system; and
- the need to interface with a myriad of physical equipments and devices to get feedback.

The combination of the above-mentioned attributes makes optimization of SFC a major challenge in terms of architecting SFC systems.

In this article, the classical centralized approaches and modern distributed approaches to SFC are presented. This is followed by an example of modern SFC to illustrate the manner in SFC systems increasingly encompass manufacturing execution system (MES) and supervisory control and data acquisition (SCADA) levels of enterprise architectures. Some recent developments in feedback control approaches for SFC are also presented along with architectural, functional, technological, and human-centric considerations.

THE CLASSICAL VIEW OF A SHOP-FLOOR CONTROL SYSTEM

The classical view of an SFC consists of an SCADA system of which the main functions are production supervision, data acquisition, and estimation of key performance indicators (KPI) and their transmission to upper decision levels. Such SCADA systems are useful to production managers for tracking customer orders and work in progress (WIP). SCADA systems are integrated into an MES to support other functions such as quality control (SPC, statistical process control) and preventive maintenance. Typically, such integration entails data transfer between an SCADA central host computer with a variety of devices including remote terminal units (RTUs), programmable logic controllers (PLCs), and operator terminals [1]. Therefore, in the classical view of SFC, its inputs are at the level of production planning (e.g., from Materials Resource Planning (MRP) level) and outputs are supervision information regarding WIP, inventory level, machine status, and performance. The resulting architecture of such classical SCADA systems is hierarchical and compliant with the federative Computer Integrated Manufacturing (CIM) concept, being monolithic (central-

Figure 1. Functioning of shop-floor control.

Figure 2. Typical SCADA architectures. *Source:* Adapted from NCS [1].

ized), distributed (using a local area network, LAN), or, more recently, networked (using a wide area network, WAN), as shown in Fig. 2. The latter introduces possible heterarchical relationships among operating systems that will be presented latter in this article.

This classical view of SFC, reducing SFC functions to supervision, low level control, and data acquisition are still considered important in process industries where the continuous and homogeneous aspects of

resources, products, and data enable global and visual supervisory human-machine interface (HMI) to be designed for decision-makers. An important aspect of SCADA systems in such industries concerns the safety of controlled processes. Modern SCADA systems are also concerned with network security, especially when they are part of a critical infrastructure such as power generation. A typical classical view of SFC using SCADA can be found in Dieu [2].

Decision-making in classical SFC using SCADA is predominantly manual (e.g., to prevent from human injuries) and automatic control is limited to physical process control (e.g., Proportional Integral Derivative (PID) control through a PLC). When applied to more complex, heterogeneous production environments, such as discrete product manufacturing systems with random disturbances, the lack of automated decision-making in classical SCADA at higher levels of production is a major short coming. This has led to the need to integrate decision-making capabilities in the control loop shown in Fig. 1. For example, Wysk and Smith [3] proposed a formal functional vision of SFC, addressing the scheduling issue using graph theory, modeling SFC as a kind of discrete event systems. Such functions are not traditionally handled in SCADA systems for the process industry, thus motivating the modern view of SFC systems, which is described in the following section.

THE MODERN VIEW OF SHOP-FLOOR CONTROL SYSTEMS

Nowadays, owing to the increase in the complexity of controlled systems, the lack of midterm range production visibility and the increase in the number and potential consequences of disruptions, it has become very desirable for SFC to have decision-making ability in order to adapt to disturbances [4]. Therefore, SFC is a key interface between systems that plan and schedule production and systems that work in real time. This evolution has been partly influenced by the Japanese way of thinking, with the just-in-time philosophy (pull systems). This philosophy implies a closed loop between production and customers; this is in contrast with the classical MRP way of thinking, which pushes products through the resources on the shop floor. In theory, there is no real need to adapt production in a system like this as all is planned and decisions are made at MRP level; thus, the SFC is only required to supervise production.

This evolution has also been made possible by the technological advances in computing and communication that allow rapid

acquisition of shop-floor status and real-time decision-making. Real time in this context means that the computational results are obtained much faster than the rate of change of shop-floor status; the decisions can thus be executed with high fidelity. Therefore, the term *control* in SFC has now evolved to mean that a higher level feedback loop operates between planning/scheduling level and real-time level, updating information, and adapting planned/scheduled production to the real situation on the shop floor. These SFC systems consider constraints that are not usually considered by planning or scheduling production systems, such as the real states of production resources, capacities, tool management, conveyor system, and inventory levels. Therefore, there is an emerging need for corresponding real-time control algorithms that maintain near-optimal performance at all times.

Consequently, modern SFC approaches integrate SCADA systems as a lower level component coupled to higher level decision-making abilities ensuring a more effective and efficient control of production resources. Typically, such high level decision-making abilities in modern SFC concern scheduling decisions, workload management, and capacity planning and tend to overlap with MES and enterprise resource planning (ERP) levels [5]. This means that traditional low level monitoring (SCADA) had to be adapted to consider this evolution. For example, if Kanban systems are used to control production resources, then its SFC system must ensure that appropriate policies are followed (e.g., no more parts than the number of Kanbans).

Figure 3 illustrates the classical hierarchical breakdown of the time horizon in production planning and control. It is inspired from the ISA-95 international standard for the integration of enterprise and control systems and the IEC 62264 international standard for enterprise-control system integration (based on the ISA-95 standard) that introduces a manufacturing operations management model [6]. In this figure, the way SFC has evolved to encompass more high level decision control loops is highlighted, leading to an approximate functional

Figure 3. Evolution of SFC. *Source:* Adapted from ISA-95 and IEC-62264.

definition of modern SFC as follows:

$$\text{Modern SFC} = \text{MES} + \text{SCADA}.$$

An important aspect of the modern SFC also concerns the control of resource efficiency. Efficiency is related to the way resources are used to attain production objectives. Efficiency considers, for example, capacity planning; maintenance KPI such as mean time to failure (MTTF), mean time to repair (MTTR), and mean time between failures (MTBF) [7, 8]; and lean/sustainability constraints such as inventory level control and power consumption control. This evolution toward “lean SFC” has been largely motivated by the Toyota way of thinking (Toyota production system, TPS), [9] which gives SFC an important role of maintaining customer satisfaction and internal efficiency. Another illustration concerns the natural integration of kaizen mechanisms within the TPS, aimed to improve KPI through minor but continuous improvement at SFC level. Kaizen decisions are clearly made at SFC level; the local quick response quality control (QRQC) decision mechanism highlights the following aspect: this mechanism basically concerns quality but QRQC decisions impact SFC as operators may modify their own production activity with regard to quality issues. Another feature of modern SFC concerns bottleneck resource management, as proposed by the theory of constraints (TOCs) [10, 11]. According to this approach, the overall effectiveness of a system is essentially guided by

its internal constraints and SFC should pay attention to these bottlenecks, controlling them accurately, ensuring that their input stock is never empty, while approximately controlling the others that are guided by the bottleneck (Drum, Buffer, and Rope). Specific scheduling rules should apply in this context and SFC must handle this aspect. Mixing the just-in-time (JIT) philosophy with the TOC and push methods is also considered in modern SFC. For example, the ConWIP method [11, 12] or demand flow technology (DFT) [13] is bridging the gap between these methods and influences the way modern industrial SFC are designed and used. Meanwhile, these industrial SFC tools are often devoted to specific shop-floor systems, such as line assembly systems within a mass customization context. The general assumption is that demand does not vary too much.

In other types of shop floors with more complex production flows (e.g., flexible manufacturing systems), or where demand varies considerably (highly customized production, niche production, etc.), the number of efficient/effective industrial tools is low and the risk is to reduce SFC to “simple” heuristic decision rules at MES level coupled with an SCADA system [7], thus implying a long-term low visibility. For this kind of SFC, research has focused on compensating this limitation because it is impractical to design standardized solutions. Formal process planning schemas for SFC have been proposed by identifying information requirements that

are unambiguously expressed as a function of the shop-floor activities required to manufacture a product [14]. This enables any generic SFC system to change its actions to flexibly manufacture different parts or the same part using different resources by appropriately modifying the information in its databases and thereby allowing real-time decision-making in the SFC to determine routing and process plans.

Typically, simulation is used to forecast the behavior of SFC, see, for example, [15], because the increasing integration of various functionalities with different time windows, decision variables, and parameters increase the decisional complexity of SFC [5]. The responsiveness of SFC can sometimes be a disadvantage because of the “nervousness” it can cause, which is a well-established issue in MRP systems. The link between SFC and planning layers was recently investigated for developing automated exception analytics systems to monitor and prioritize shop-floor exceptions systematically based on a postoptimality analysis of plans being executed [16].

Other research approaches based on simulation range from capacity planning in ERP to real-time feedback control to compensate for random perturbations [17]. Treating SFC as a continuous variable control problem in which timing of discrete events is controlled has led to a body of work in which controllers can be highly distributed for real-time scheduling [18–20]. This continuous variable SFC approach lends itself to real-time decision-making for routing and process parameters [20, 21]. The resulting dynamics can be analyzed using control theoretic techniques and have been proved to be globally stable for general shop-floor configurations including job-shop-like configurations with dissimilar machines with alternate routings without any restrictive assumptions [22].

AN ILLUSTRATIVE EXAMPLE OF A MODERN SFC SYSTEM

The AIP-Primeca FMS cell is a shop floor located at the University of Valenciennes and Hainaut-Cambr sis (France). This cell was built with the following industrial components:

- A monorail conveyor system with 15 single-direction shuttles [RFID (radio-frequency identification) tagged] and 11 transfer block (TBs) permitting flexible routing inside the cell.
- Seven robotized workstations (WSs) located at specific points on the monorail, which perform automated operations (loading/unloading, assembly, and quality inspection) on the product being manufactured. Loading/unloading consists in loading/unloading a plate on a shuttle, the plate being the support on which the products are made.

Thus, each product is placed on a dedicated shuttle and the set moves from WS to WS. Figure 4 provides an overview of the WSs, their locations, and the conveyor system.

The corresponding SFC architecture, shown in Fig. 5, is based on the “distributed SCADA architecture” shown in Fig. 2 and is augmented with functionalities at MES level. It is composed of the following four levels:

- Levels 0 and 1 are built with mechanical operating systems (St ubli and Kuka robots; Cognex vision inspection; Montratec monorails, transfer gates, and positioning units), PLCs (750-841 Wago controllers programmed with Codesys), stop and go shuttle devices, RFID R/W (Schneider OsiSense XG), and Ethernet switched automation network.
- Level 2 consists in an OPC server (Schneider OFS), several supervisory stations (equipped with Arcinfo PcVue32), a log server (SQL database server), and an Ethernet area operation information network.
- Level 3 is essentially composed of an MES system including scheduling ability optimization (IBM ILOG CPLEX Optimization Studio).

Typically, the problems to be solved by the SFC system in this cell include:

Figure 4. Overview of the AIP cell.

- the scheduling of a limited amount of resources (WSs, shuttles, inventory, and tools) within the time given to make a dynamic set of products;
- the dynamic routing of shuttles containing the WIP;
- the real-time control of WS and transfer gates.

Using this SFC architecture:

- Levels 0 and 1 manage the shuttle routing and WS states in real time.
- Level 2 supervises and monitors the WIP and interfaces levels 1 and 3.
- Level 3 defines the operations to be carried out by WS at levels 0 and 1.

More details about the SFC used in this research can be found in Berger *et al.* [23].

CURRENT RESEARCH IN SHOP-FLOOR CONTROL SYSTEMS

The modern view of an SFC can be seen as a first step toward increased local decision-making capability where events occur and

reactivity is needed. There are several major challenges from a scientific and practical perspective. Some are provided in this section and organized according to architectural, functional, and technological considerations.

Architectural Considerations

Classical hierarchical architectures are rapidly evolving toward more distributed/heterarchical SFC architectures, typically by extending the SCADA architecture. The basic idea is to integrate redundancy in the control decision abilities and horizontal cooperation mechanisms in the control decision process among decisional active or intelligent entities, that is, resources, products, inventories, tools, and so on. The aim is to limit the risks of local controller loss (robustness to failure and ease of restarting) and to enable more “plug and control” approaches making the whole SCADA system more capable of self-reconfiguring as well as self-adapting to changes in the environment and in the production system [24]. This also implies focusing on work at MES level to fine-tune this integration [25].

Figure 5. Modern SFC architecture of the AIP cell.

Functional Considerations

The idea is to integrate more functional abilities in SFC to encompass broader time horizons and increased data space for better decisions. This could lead to the integrated cohesive optimization of maintenance, production, and inventory, which are otherwise treated in isolation. The study of robustness is also important nowadays, typically in reactive production scheduling [26]. This issue is increasingly addressed from an operation research point of view. The coupling of optimization and simulation tools in the global context of digital enterprise also seems promising [27, 28].

Integrating intelligence and activeness into entities composing an SFC system (products, resources, inventories, tools, etc.) seems to be another promising research area [29].

From an information management point of view, it would help improve tracking the history of events and use of resources [30]. From an energy management point of view, it would help integrate opportunistic energy gains and improve management of energy costs given the increasing lack of visibility in terms of energy supply (variability of renewable energy power and variability in grid energy costs) [31].

Technological Considerations

Service orientation technology and service-oriented architectures (SOA) is key in the evolution of SFC [32]. Indeed, it enables a “components off the shelves” approach to be used that is required when designing plug and control SFC enabling “plug and produce” production systems [33].

As an illustrative example, the EU FP7 project IMC-AESOP (www.imc-aesop.eu) aims at defining the next generation of SFC systems based on SOA and recent internet technology such as cloud computing and the internet of things (Internet of Things (IoT) [34].

The IoT and ambient intelligence are also technological solutions enabling the improvement of emerging SFC systems and architectures. This evolution will contribute to design more self-adapting, self-organized SFC [35].

Toward More Human-Centered SFC

Human operators know information the SFC system does not know. Typically, such information comes from outside the SFC system itself, and by interaction with the SFC system, operators could help constrain or bound automated decisions according to this knowledge, thus anticipating events. For example, an important incoming order not yet integrated in the production planning, an operator that suspects a production machine will operate defectively (e.g., furtive error), or a possible incoming supplier strike can be considered through such interaction. In addition, despite all the theoretical developments in learning systems, the human operator is still more able of learning, adapting, and reasoning than computerized systems. Human operators can identify repetitive patterns in production, for example, and can use them to anticipate events or to optimize production over broader time windows.

Consequently, keeping operators in the SFC decisional loops shown in Fig. 1 is still relevant. All the research in these different areas (architectural, functional, and technological considerations) could lead to more human-centered and cognitive SFC systems [36] as the knowledge of human operators shall be merged more easily with the knowledge constructed by various active/intelligent interacting entities rather than in purely centralized SFC approaches. The technology currently available enables this smart integration. Now, time has come for researchers to reintegrate human operators in the loop; fully automated shop floors with nobody inside are no longer considered. However, the interaction of emerging SFC

systems with human operators is still poorly addressed by researchers.

INTRODUCTION TO STOCHASTIC APPROXIMATION

GEORGE YIN
Department of
Mathematics, Wayne
State University,
Detroit, Michigan

Stochastic approximation (SA) methods were introduced by Robbins and Monro in their pioneering work in 1951 [1]. The original aim was to locate zeros of a nonlinear continuous function. That is, to find the roots $f(x) = 0$ when either the precise form of this function is unknown, or it is too complicated to compute, but one is able to take “noisy” measurements or observations at desired values. The procedure is known as the *Robbins–Monro (RM) algorithm*. The suggested solution method is a stochastic recursive algorithm.

A classical example is to find the appropriate dosage level of a drug, provided only $f(x)$ +noise is available, where x is the level of dosage and $f(x)$ is the probability of success leading to the recovery of the patient at dosage level x . In 1952, Kiefer and Wolfowitz proposed another algorithm that is concerned with the minimization of a real-valued function using only noisy functional measurements [2]. That algorithm is commonly referred to as the *Kiefer–Wolfowitz (KW) algorithm*.

Soon after, researchers realized that SA algorithms can be applied to a wide variety of situations in optimization and in systems with a “control” parameter. Owing to its importance, SA has had a long history and has attracted much attention in the past five decades. Significant progress has been made in the study of such stochastic recursive algorithms. The interesting theoretical issues in the analysis of iteratively defined stochastic processes focus on the basic paradigm of stochastic difference equations.

Much of the development has originated from a wide range of applications in optimization, control theory, economic systems, signal processing, communication theory, learning, pattern classification, neural network, and many other related fields. A number of monographs have been written, each of which has its own distinct features; for instance, the books of Albert and Gardner [3], Wasan [4], Nevel’son and Khasminskii [5], Kushner and Clark [6], Benveniste *et al.* [7], Chen [8], and Kushner and Yin [9].

HISTORICAL DEVELOPMENT

To put things in the historical perspective, we may divide the development of the SA methods into several periods. Since SA is a recursive scheme, convergence and rates of convergence are crucial. In the early development around 1950s and 1960s, mainly basic probabilistic tools and traditional statistical assumptions such as independent and identically distributed noise, together with certain restrictions on the functions such as assuming $f(x)$ to be monotone were used. In the original work [1], convergence in probability was obtained.

Summarizing much of the early historical development, the book [4] included the with probability one (w.p.1) convergence proof for multidimensional problems of Blum, the asymptotic normality study of Sacks, and the work of Fabian, among others. People soon recognized that the SA algorithms are closely related to stochastic dynamic systems. As a representative, Nevelson and Khasminskii’s book [5] treated SA as stochastic processes and dealt with martingale difference type noise. The use of Liapunov function was also brought in, together with recursive estimation.

As time went on, many applications arising in control and optimization forced researchers to reexamine the algorithms in which the noise encountered was correlated.

In the mid 1970s, Ljung studied the problem from a dynamic system point of view [10]. The idea is that in lieu of the discrete recursion, one treats a continuous-time dynamic system given by an ordinary differential equation (ODE). For example, for the root finding problems, once the associated ODE is obtained, the roots being sought become stable points of the associated ODE. Such an idea was further developed in Ref. 6. By combining analysis and probabilistic argument, Kushner and Clark set up a framework by considering asymptotic properties of suitably scaled sequences. The work of Benveniste *et al.* [7] emphasized the close connection of SA and adaptive systems. One of the distinct features is the use of Markovian setting and the treatment of the Poisson equations. In addition, it exploits many identification, estimation, and tracking problems. The book by Chen [8] summarizes the work of using random varying truncation bounds developed by Chen and Zhu; it also provides trajectory subsequence-based convergence proof. The work of Kushner and Yin [9] presents a comprehensive development of the modern theory of SA and recursive stochastic algorithms for both constrained and unconstrained algorithms, with step sizes that either go to zero or are constant and small, and possibly random.

More recently, SA techniques have been employed in the analysis of simulated annealing type of global stochastic optimization problems [11]; emerging applications have also been found in wireless communications (9,12, Chapter 3), discrete optimization [13], financial engineering [14], and so on. For a wide range of connections of SA to simulated annealing, temporal difference algorithms, Markov chain Monte Carlo, experimental design, and so on, and general stochastic search and optimization, the reader is referred to Ref. 15.

ALGORITHMS

RM Algorithm

We begin with the RM algorithms for finding zeros of a nonlinear function. Let $f : \mathbb{R}^r \mapsto \mathbb{R}^r$ be a continuous function. We wish to find

$f(x) = 0$, but only noisy measurements

$$y_n = f(x_n) + \xi_n$$

are available, where $\{\xi_n\}$ denotes a sequence of random noise. Note that n is a positive integer referred to as *discrete time*, representing the iteration number. The algorithm proposed by Robbins and Monro takes the form

$$x_{n+1} = x_n + a_n y_n, \quad (1)$$

where $\{a_n\}$ is a sequence of nonnegative real numbers satisfying $a_n \rightarrow 0$ as $n \rightarrow \infty$, $\sum_n a_n = \infty$, and $\sum_n a_n^2 < \infty$. The sequence $\{a_n\}$ is usually referred to as a *sequence of step sizes* or *gains*. The conditions on the step sizes indicate that they cannot be too small. If they are too small (i.e., $\sum_n a_n < \infty$), then the iterates may not ever converge to the desired value. To see this, take the noise-free case $\xi_n = 0$ and suppose that $f(\cdot)$ is a bounded function. Then

$$\begin{aligned} \left| \sum_{j=0}^{\infty} [x_{j+1} - x_j] \right| &\leq \sum_{j=0}^{\infty} |x_{j+1} - x_j| \\ &\leq \sum_{j=0}^{\infty} a_j |f(x_j)| \leq \kappa. \end{aligned}$$

[Here and throughout the paper, $\kappa > 0$ is used as a generic constant; its value may change for different usage. Thus by our convention, $\kappa + \kappa = \kappa$ and $\kappa \kappa = \kappa$.] The above argument indicates that $\sum_j (x_{j+1} - x_j)$ converges absolutely. On the other hand, by telescoping

$$\sum_{j=0}^n [x_{j+1} - x_j] = x_{n+1} - x_0.$$

Thus $x_n \not\rightarrow x^*$, the true parameter that we are approximating unless x_0 is sufficiently close to x^* .

KW Algorithm

Here, we wish to minimize a real-valued function $f(x) : \mathbb{R}^r \mapsto \mathbb{R}$ based on noise-corrupted observations $F(x, \zeta_n)$ with $EF(x, \zeta_n) = f(x)$,

where $\{\zeta_n\}$ represents the noise. The difficulty is that we know neither the form of $F(\cdot)$ nor $f(\cdot)$. To approximate the minimizer, we use the finite difference approximation to the gradient of $f(x)$. Denote the finite difference interval by $\{c_n\}$ (with $c_n \rightarrow 0$ as $n \rightarrow \infty$). Use x_n to denote the n th estimate of the minimum. Suppose that for each i and each n , we observe

$$y_{n,i} = -\frac{F(x_n + c_n e_i, \zeta_n^+) - F(x_n - c_n e_i, \zeta_n^-)}{2c_n},$$

where $\zeta_n^\pm$ are random noise sequences. Denote $y_n = (y_{n,1}, \dots, y_{n,r})$. Then the approximation algorithm is again given by $x_{n+1} = x_n + a_n y_n$, which is of the same form as that of Equation (1). By introducing

$$\xi_n = (\xi_{n,1}, \dots, \xi_{n,r}), \beta_n = (\beta_{n,1}, \dots, \beta_{n,r}),$$

with

$$\begin{aligned} \xi_{n,i} &= \left[f(x_n + c_n e_i) - F(x_n + c_n e_i, \zeta_{n,i}^+) \right] \\ &\quad - \left[f(x_n - c_n e_i) - F(x_n - c_n e_i, \zeta_{n,i}^-) \right], \\ \beta_{n,i} &= f_{x_i}(x_n) - \frac{f(x_n + c_n e_i) - f(x_n - c_n e_i)}{2c_n}, \end{aligned}$$

where $f_{x_i}(\cdot)$ denotes the gradient of $f(\cdot)$ w.r.t. x . Now the above algorithm can be rewritten as

$$x_{n+1} = x_n - a_n f_x(x_n) + a_n \frac{\xi_n}{2c_n} + a_n \beta_n. \quad (2)$$

In the above, ξ_n represents the noise, β_n denotes the bias, $c_n \rightarrow 0$, and $\sum_n \frac{a_n^2}{c_n^2} < \infty$. We have used two-sided finite difference. One-sided finite difference can also be used. However, in practice, the two-sided finite difference method appears to be more preferable since it has smaller bias. This is easily seen by taking a Taylor expansion of the finite difference quotient in β_n . In the above discussion, we assumed f being smooth. When this condition is violated, the subgradient can be used in lieu of the gradient; see Kushner and Yin [9].

More General Algorithms and Variants

In various applications such as those arising in signal processing and adaptive controls, one often needs to treat stochastic approximation algorithms with noise having a more complex structure of the form

$$x_{n+1} = x_n + a_n f(x_n, \xi_n). \quad (3)$$

Including both Equations (1) and (2) as special cases, such algorithms arise, for example, in “equalization” filters in communication channels, adaptive antenna array processing, and so on (9, Chapter 3). In addition, $f(\cdot)$ can also depend on n :

$$x_{n+1} = x_n + a_n f_n(x_n, \xi_n). \quad (4)$$

To track slight parameter variations, one often uses an algorithm with constant step size of the form

$$x_{n+1} = x_n + \varepsilon f_n(x_n, \xi_n), \quad (5)$$

where $\varepsilon > 0$ is a small parameter. Because of the constant step size used, a pertinent notion of convergence is in the sense of weak convergence of probability measures (9, Chapter 7). Such constant step size algorithms are particularly suitable for tracking slight time-varying parameters. Suppose that H is a constraint set. We require the iterates to be in the set. Write the algorithm as

$$x_{n+1} = \Pi_H(x_n + a_n f(x_n, \xi_n)), \quad (6)$$

where Π_H denotes the projection onto the constraint set H . If the iterate is within the projection region, we simply keep the recursion running; if it is outside the region, we project it back. Define a “reflection” or correction term z_n as

$$a_n z_n = x_{n+1} - x_n - a_n f(x_n, \xi_n),$$

that is, it is the vector of the shortest Euclidean length needed to take $x_n + a_n f(x_n, \xi_n)$ back to the constraint set H if it is

not in H . Using this notation, Equation (6) can be rewritten as

$$x_{n+1} = x_n + a_n f(x_n, \xi_n) + a_n z_n. \quad (7)$$

The constraint set can be as simple as a rectangular region, or as complex as a complicated set bounded by nonlinear functions; see Section 4.3 of Ref. 9 for various possible projection regions.

In addition to the algorithms mentioned above, many other variants have been studied. For example, if one can get the observation y_n but the sequence $\{x_n\}$ emerges in a random manner and is not at one's disposal, then one is in the so-called passive SA framework. Sometimes, we may wish to use constraints but wish to relax the "hard constraints," and allow them to be violated slightly from time to time. Roughly speaking, such constraints are "soft constraints." In addition, as was mentioned earlier, one may also define a sequence of randomly generated truncation bounds. This will enable one to relax the conditions on the growth rates of the function under consideration or the *a priori* knowledge of the constraint set.

CONVERGENCE AND RATES OF CONVERGENCE

Convergence

To study the convergence of the algorithm, we use the ordinary differential equation method. Instead of working with the discrete iteration directly, we take a continuous-time interpolation. To get some insight, we first give some heuristic argument.

Consider Equation (1). Suppose that the function $f(\cdot)$ is continuous. Although rather complex noise processes can be dealt with [9], for simplicity, in this survey, we assume the measurement or observation error is a sequence of independent and identically distributed random variables. Also, for simplicity, assume the iterates $\{x_n\}$ are bounded. The boundedness assumption is not crucial but can simplify the presentation here; a more general treatment is given in

Ref. 9. Choose a small $\Delta > 0$ such that

$$\sum_{j=n}^{n+m_n^\Delta-1} a_j \approx \Delta, \text{ or equivalently}$$

$$m_n^\Delta = \max \left\{ m; \sum_{j=n}^{n+m-1} a_j < \Delta \right\}.$$

Iterating on Equation (1) yields

$$x_{n+m_n^\Delta} = x_n + \sum_{j=n}^{n+m_n^\Delta-1} a_j f(x_j) + \sum_{j=n}^{n+m_n^\Delta-1} a_j \xi_j.$$

For Δ small enough, and for $n \leq j \leq n + m_n$, $f(x_j)$ is "close" to $f(x_n)$ by the continuity. As a result

$$\sum_{j=n}^{n+m_n^\Delta-1} a_j f(x_j) \approx \sum_{j=n}^{n+m_n^\Delta-1} a_j f(x_n) \approx \Delta f(x_n),$$

and

$$x_{n+m_n^\Delta} - x_n \approx \Delta f(x_n) + \text{error}.$$

To see the size of the error, we compute its variance:

$$\begin{aligned} \text{Var}(\text{error}) &= \text{Var} \left(\sum_{j=n}^{n+m_n^\Delta-1} a_j \xi_j \right) \\ &= O \left(\sum_{j=n}^{n+m_n^\Delta-1} a_j^2 \right) = O(\Delta a_n). \end{aligned}$$

Therefore,

$$\frac{x_{n+m_n^\Delta} - x_n}{\Delta} \approx f(x_n) + \text{error with diminishing variance}.$$

Over a small interval, the mean change of the values of the parameter is much more important than that of the noise. The noise is averaged out in the limit, and the asymptotic behavior can be approximated by the ODE

$$\dot{x} = f(x). \quad (8)$$

If a projection algorithm is used, one obtains a projected ODE [9].

To prepare us for the study of the desired asymptotic properties, let us recall the notion of equicontinuity. Use $C([0, \infty) : \mathbb{R}^r)$ to denote the family of $\mathbb{R}^r$ -valued continuous functions defined on $[0, \infty)$. Let $\{f_n\}$ be a sequence of $\mathbb{R}^r$ -valued functions on $[0, \infty)$. It is said to be *equicontinuous* in $C([0, \infty) : \mathbb{R}^r)$, if $\{f_n(0)\}$ is bounded and for each T and $\varepsilon > 0$, there is a $\delta > 0$ such that for all n

$$\sup_{|t-s| \leq \delta, |t| \leq T} |f_n(t) - f_n(s)| \leq \varepsilon. \quad (9)$$

The well-known *Ascoli–Arzelá* Theorem states as follows: Let $\{f_n(\cdot)\}$ be a sequence of functions in $C([0, \infty) : \mathbb{R}^r)$, and let the sequence be equicontinuous. Then there is a subsequence that converges to some continuous limit, uniformly on each bounded interval.

For the SA algorithm, take piecewise linear interpolations and define

$$\begin{aligned} t_n &= \sum_{j=0}^{n-1} a_j, \quad m(t) = \max\{n : t_n \leq t\}, \\ x^0(t_n) &= x_n, \quad x^0(t) = \frac{t_{n+1} - t}{a_n} x_n + \frac{t - t_n}{a_n} x_{n+1}, \\ &\quad t \in (t_n, t_{n+1}). \end{aligned}$$

That is, the interpolation interval is $[t_n, t_{n+1})$. Next, to bring the asymptotic behavior of the process to the foreground, define a shifted sequence by $x^n(t) = x^0(t + t_n)$. Under suitable conditions, it can be shown that $\{x^n(\cdot)\}$ is uniformly bounded and equicontinuous. By the *Ascoli–Arzelá* Theorem, we can extract a convergent subsequence $x^{n_k}(\cdot)$ such that $x^{n_k}(\cdot) \rightarrow x(\cdot)$. Then, we characterize the limit $x(\cdot)$ and prove that it is nothing but the solution of the ODE (Eq. 8). Concerning the limit differential equations, we note that the stationary points of Equation (8) are exactly the roots of $f(\cdot)$ that we are searching for. If x^* is the unique asymptotically stable point of Equation (8), then we can show the iterates $x_n \rightarrow x^*$ w.p.1. If instead of a single point x^* , Z is a set of zeros of $f(\cdot)$ such that Z is asymptotically stable in the sense of Liapunov, then $x_n \rightarrow Z$ w.p.1.

In applications, it is often more convenient to work with piecewise constant interpolations. To use such an interpolation, we

need to modify and extend the definition of the equicontinuity. In (p. 102 of Ref. 9), an extension, known as *equicontinuity* in the extended sense was given. Then a version of the *Ascoli–Arzelá* Theorem for sequences of functions that are equicontinuous in the extended sense can be used, which facilitates the analysis for piecewise constant interpolated sequences.

Rates of Convergence

Suppose that $x_n \rightarrow x^*$ (the true parameter) w.p.1 as $n \rightarrow \infty$. Then one is interested in the rate of convergence. For SA, what do we mean by “rate of convergence?” Consider, Equation (1) for instance. To study the convergence rate, we take a suitably scaled sequence $u_n = (x_n - x^*)/a_n^\alpha$, for some $\alpha > 0$. In case of constant step size algorithm, this is changed to $(x_n - x^*)/\varepsilon^\alpha$. If α is chosen such that u_n converges in distribution to a nontrivial limit, the scaling factor α together with the asymptotic covariance of the scaled sequence gives us the rate of convergence. That is, the scaling α tells us the dependence of the estimation error $x_n - x^*$ on the step size, and the asymptotic covariance is a mean of assessing “goodness” of the approximation.

It turns out that a suitable scaling for Equation (1) is $\sqrt{a_n}$. If a constant step size algorithm is used, the scaling is $\sqrt{\varepsilon}$. To illustrate, consider Equation (1) with $a_n = 1/n$. Assume $f(x) = H(x - x^*) + O(|x - x^*|^2)$ such that $\tilde{H} = H + I/2$ is a stable matrix (i.e., all of its eigenvalues have negative real parts). The rate of convergence is based on local analysis. Using the definition u_n together with Equation (1), we obtain

$$u_{n+1} = u_n + \frac{1}{n} \tilde{H} u_n + \frac{1}{\sqrt{n}} \xi_n + O\left(\frac{1}{n} |u_n|^2\right).$$

The last term above is asymptotically unimportant (i.e., its limit will be 0 in an appropriate sense). Thus we can ignore it. Owing to the presence of $\sqrt{n}$, the noise is not going to be averaged out. We need to deal with $\sum_{k=1}^n \xi_k / \sqrt{k}$. This term is asymptotically equivalent to $\sum_{k=1}^n \xi_k / \sqrt{n}$, which can be further characterized by a normal distributed random variable with covariance

$\Sigma = E\xi_1\xi_1'$ by the well-known central limit theorem.

With more effort, we can even obtain a limit stochastic differential equation. To see this, define a piecewise constant interpolation $u^n(0) = u_n$ and $u^n(t) = u_k$ for $t \in [t_{k+n} - t_n, t_{k+n+1} - t_n)$. It can be shown that for $\ell \geq 1$, $\sum_{k=\ell}^{\ell+m(t)-1} \frac{1}{\sqrt{k}} \xi_k$ converges weakly to a Brownian motion $\tilde{w}(\cdot)$ with covariance Σt . We can further rewrite the $\tilde{w}(\cdot)$ in terms of the standard Brownian motion $w(\cdot)$ as $\tilde{w}(t) = \Sigma^{1/2} w(t)$. Furthermore, it can be shown that $u^n(\cdot)$ converges weakly to the solution of the stochastic differential equation

$$du = \tilde{H}u dt + \Sigma^{1/2} dw.$$

Note that the above stochastic differential equation is linear in u , and, as a result, it has a unique solution for each initial condition u_0 . The limit stochastic differential equation gives a better description of the dynamics of the suitably scaled estimation errors. We refer the reader to Chapter 8 of Ref. 9 for further reading. Denote the asymptotic covariance by S . Then it can be shown that S satisfies the following Liapunov equation:

$$\tilde{H}S + \tilde{H}'S = -\Sigma.$$

This further implies that under suitable conditions, $\sqrt{n}(x_n - x^*)$ converges in distribution to a normal random variable $N(0, S)$, which gives us the desired rate of convergence.

ASYMPTOTIC OPTIMALITY OF PERFORMANCE

One of the most important matters is to improve the performance of SA algorithms. Let us consider KW algorithms. Each step of the KW algorithm uses $2r$ observations (if two-sided finite difference is used). Thus $2r$ steps are needed to get a derivative estimate. An alternative method is to update only one direction at each iteration using a finite difference estimate and to choose the direction randomly at each step. This results in using only two observations at each step. Such an idea appeared in Ref. 6 together with

the associated convergence and rate of convergence results. At that time, it was noted that if the random directions are chosen at the unit sphere, then there is a small advantage as compared to the KW method. The work of Spall [16] indicated that if the random directions are chosen on the unit cube, then the performance is better than the KW algorithms; this is a significant discovery and enables one to treat high dimensional problems effectively. In fact, it was noted in Ref. 16, one can “arbitrarily” distribute perturbations, but the Bernoulli case (unit cube) has special optimality properties and is easier to implement.

Along another line in the late 1980s, Polyak [17] and Ruppert [18] independently discovered that averaging can help to improve the efficiency of SA algorithms. The main idea is to first generate a sequence of rough estimates using large step sizes and then average the resulting estimate to smooth things out. The algorithm is given by

$$\begin{aligned} x_{n+1} &= x_n + \frac{1}{n^\gamma} (f(x_n) + \xi_n), \\ \bar{x}_{n+1} &= \bar{x}_n - \frac{1}{n+1} \bar{x}_n + \frac{1}{n+1} x_{n+1}, \end{aligned} \quad (10)$$

where $1/2 < \gamma < 1$. It can be shown that such algorithms are asymptotically optimal in that they have the best scaling α and the smallest variance (9, Chapter 11); see also Yin (20). One may find discussion of the related finite-sample performance of the iterate averaging in Ref. 15 (Section 4.5.3). Moreover, the efficiency issue can also be studied in connection with the Cramér–Rao bounds [5].

The setting of SA can be carried over to infinite-dimensional spaces; for example, Banach spaces and/or Hilbert spaces. In addition to the pure mathematical interest, the motivation of the study stems from the fact that in various optimization problems, the solutions of the problems involve finding the root or the optimum for points not living in Euclidean spaces, but in function spaces. In this article, we focus on finite-dimensional cases. For infinite-dimensional problems, we refer the reader to Ref. 19 and the many references therein.

SUMMARY

To summarize, SA methods have been the subject of an enormous volume of research, both theoretical and applied, for five decades. Owing to the vast amount of literature accumulated, it is very difficult or virtually impossible to provide an exhaustive list of references on stochastic approximation. It is likewise very difficult to give an extensive account of the technical development in a survey paper of this scale. As a result, we chose the road of discussing the main ideas and left most of the technical details aside. Appropriate references have been provided. Our hope is that with the references provided at the end of this article, the reader will be able to pick out references suitable for his/her needs.

INTRODUCTION TO THE USE OF LINEAR PROGRAMMING IN STRATEGIC HEALTH HUMAN RESOURCE PLANNING

MARIEL S. LAVIERI

Effective human resource planning decisions are fundamental to achieving sustainable healthcare systems. The value of health professionals is undeniable, and a shortage of workers significantly affects the number of patients that can receive healthcare, the quality and effectiveness of the services provided, workforce attrition rates, and the length of time patients must wait for such care [1]. Health human resource (HHR) planning goals include identifying and achieving “the optimal number, mix, and distribution of personnel at a cost society is able to afford” [2]. Decision models that integrate elements such as the supply of and demand for providers, along with economic considerations, are crucial for effective HHR planning.

Decisions related to workforce supply have long-term implications. It takes time to educate sufficient numbers of health professionals to replace those who retire. Educating each health professional represents a significant societal financial investment. Admitting too many students is therefore not desirable; it is important that each newly graduated healthcare professional is able to take up a position in the healthcare system. Balancing the number of educational seats with the

in-migration of health professionals, while accounting for the impact of other factors (such as working hours, attrition from the educational programs, and productivity [3]) on the supply of professionals, needs to be considered.

Identifying the “optimal” number and mix of HHR has been repeatedly highlighted as a necessary goal of planning [2, 4]. However, the determination of the “optimal” number and mix of providers (i.e., the number and mix of HHR resources that are able to achieve best outcomes) will vary, and it is dependent on how need and demand for providers is defined. Most methods and models used in practice focus on limited or narrow aspects of planning, and they do not consider the multiple factors and contexts that can influence supply and demand. For example, forecasting models are often produced in isolation of their economic implications and may lead to recommendations that might be believed to be inconsistent with fiscal goals of decision makers. They are perceived as unrealistic because of the constraints in other sectors of the HHR planning system. The models often project estimates for providers holding conditions such as healthcare utilization constant [5]. Further, decisions made today about numbers of education seats, changes in employment positions, or strategies to retain professionals (e.g., decreasing attrition rates) are often examined in isolation.

This article presents an overview of long-term HHR planning models and an introduction to how linear programming may be used to model strategic HHR decisions faced by large-scale healthcare systems. The remainder of this article is organized as follows. This article starts with an introduction to strategic HHR models. The following section provides examples of strategic workforce planning models within the operations research literature. The next section describes in further detail the linear programming approach and key inputs and outputs to consider in such models. We

conclude by summarizing this article and discussing modeling considerations.

HEALTH HUMAN RESOURCE PLANNING MODELS

Given the importance of decisions related to the appropriate supply of professionals to meet demand, various models to estimate the supply and demand have been developed. Approaches to planning HHR have largely focused on physicians and nurses and have been primarily based on supply projections [6]. Historically, provider-to-population ratios have been utilized to project the demand for physicians and nurses. As the collection and availability of data about health professionals have improved, methods to estimate the future supply of health professionals have evolved in their sophistication. Advances in other fields (as well as improvements in computational power) have played a role in the evolution of HHR planning models.

An inventory of key HHR planning models from various jurisdictions across Canada was conducted by Health Canada [7]. It is based on the classification suggested by O'Brien-Pallas *et al.* [6], which distinguishes between three types of models: *supply models*, *demand models*, and *econometric models*. *Supply models* focus on calculating available future resources. They include those proposed in the 1980s by Kazanjian *et al.* [8] and Kazanjian *et al.* [9] as well as models such as [10] and [11] that estimate the number (or utilization) of future health professionals based on descriptions of current workforce characteristics, expected entries, and attrition. More basic supply models (such as Archambault [12]) extrapolate from current conditions based on the growth, and in some cases the cyclical components, of the health workforce. *Demand* (or needs-based) *models* such as [13] and [14] focus on planning the HHRs needed based on general population demographics and health status indicators. Finally, the so-called *econometric approaches* (or resource allocation models), such as Dickson [15], attempt to determine the feasibility of various scenarios based on

the calculation of the associated costs or the application of costs as a constraint.

Although these models provide a starting point to better understand supply and demand for health professionals, none is sufficient on its own to address the current and future challenges of planning the health workforce. Supply models assume that the status quo is appropriate when determining future supply. Demand models concentrate on future health professional requirements, taking supply projections as a given. They do not incorporate the ability of the decision maker to control supply to meet those requirements. They take current supply as a starting point for the estimates, regardless of whether the current supply is sufficient or appropriate. They also assume that current demand is predictive of future demand without considering the changing health status of the population (such as changes in life expectancy, the prevalence of risk factors, or interventions such as self-care or technological advances). Finally, resource allocation approaches determine requirements based on anticipated future costs or financial resources and often do not consider population health needs.

Policy decisions about HHRs can have significant effects on their supply and deployment. An important objective of any effective modeling approach is to identify relevant scenarios and those factors that influence the scenarios. Simulation models are increasingly being used to examine the impact of recruitment and retention strategies on supply and demand [16, 17]. In contrast to how this term is used in operations research [18], simulation here involves projecting the nursing work size based on a proposed plan. On the basis of current demographics (such as workforce entry and attrition), simulation is used to determine the impact of a given plan on population health indicators. This approach assumes that the decision maker is able to derive (in multiple tries) a plan that is both feasible and meets the recognized needs.

EXAMPLES OF RESOURCE PLANNING MODELS WITHIN THE OPERATIONS RESEARCH LITERATURE

Within the operations research context, various approaches have been developed to guide strategic workforce decisions. Among others, models have been applied in the long-term planning of military human resources [19], planning of personnel and determining optimal staffing policies in call centers [20], and industries including chemical [21] and aerospace, automotive, machine tool and, semiconductor [22]. Such models demonstrate the capacity of using operations research to guide workforce planning decisions. However, there continues to be great potential to further incorporate the intricacies of the healthcare system in the long-term human resource models developed.

The approach used will depend on the question addressed. For instance, in modeling, the size and composition of a workforce, newsvendor-type staffing models are used to incorporate stochastic effects such as absences and wastages [23] as well as demand uncertainty [24], whereas forecasting and queuing models provide insights into the relationship among workers available and delays in the system [25], bottlenecks [26], and the need for temporary personnel [27]. Integer and mixed-integer programs are often used to model the tasks performed by each worker, which may involve movement restrictions between workstation groups [28] and restrictions in skill acquisition [29]. Simulation and system dynamics models (such as Vanderby *et al.* [30]) enable the incorporation of feedback loops and other complexities of the system. For higher level planning, dynamic programming (such as [31, 32]) and linear programming (such as [33–37]) may be used to model workforce training, promotion, and recruitment decisions. While dynamic programming (deterministic or stochastic) has the ability to model the exact number of workers in the system, it suffers from the curse of dimensionality. Alternatively, for large healthcare systems, a linear programming approach may be used to gain insights into the system. Notice that a linear program (LP) will not

restrict variables to be integers, yet such an approximation may be appropriate when dealing with large systems.

In the remaining sections, we focus on the linear programming approach but encourage the interested reader to review other approaches described in this section and to select the approach that best fits their modeling needs.

A LINEAR PROGRAMMING APPROACH

A LP is a mathematical tool that enables “the planning of activities to obtain an optimal result, that is, a result that reaches the specified goal best among all feasible alternatives” [38]. Desirable features of an LP are that it:

- Finds the best solution possible to meet given targets and does not rely on judgment or trial and error to find a good solution.
- Takes only seconds to solve, which is ideal for investigating various scenarios and performing sensitivity analyses.
- Has a strong mathematical foundation to support the decision-making process.

Different from the HHR models described, a linear programming approach does not take possible educational plans as inputs to identify the impact on vacancies or population health, rather it allows the decision maker to choose desired minimum targets (which could be determined through various demand or needs-based approaches) and then determine the optimal way of meeting those targets, by providing an optimal education, promotion, and recruitment plan. Such a model combines characteristics of the three types of HHR models described. From the supply models, it considers the current supply and attrition rates to track the number of workers of each age in the workforce. It encompasses demand models by constraining the number of health professionals that are needed in the system to meet population needs. Finally, it compares *all* feasible plans to determine an optimal strategy that is one that achieves a supply–demand balance at the least financial cost to the system and meets the growing

demand for healthcare providers. When a decision maker provides a scenario (i.e., a set of assumptions about the future), a linear programming model provides an optimal plan under that scenario, hence enabling the decision maker to interactively investigate the impact of the assumptions.

An LP has three main components: decision variables, an objective function, and a set of constraints. It determines values for the decision variables so that the objective function is as high or low as possible (depending on whether the decision maker seeks to minimize or maximize the objective) while simultaneously ensuring that all constraints are satisfied. Therefore, rather than relying on multiple tries in search of a strategy that will both meet a set of requirements and be as good as possible, the mathematical structure of the LP ensures this.

Lavieri and Puterman [33] provide an example of the mathematical formulation for such a model. The decision variables in the example are the number of students admitted ($s(.)admitted_j$), the workforce recruited ($n(.)recruited$), and the workforce promoted ($n(.)promoted_j$) in year j of the planning horizon ($1 \leq j \leq N$, where N represents the length of the planning horizon). These decision variables may be used to calculate the total number of students $s(.)_j$ and workers $n(.)_j$ in the system and are nonnegative. As shown in Lavieri and Puterman [33], the decision variables can be modified to incorporate educational programs of different lengths (which is common in HHR planning) as well as different levels of workforce (such as managers and senior managers).

Once the decision variables have been defined, the planner must choose the objective function (which will be used to evaluate the feasible solutions). An objective function often used in HHR planning is to minimize the total cost incurred over the planning horizon. If we account for the training cost associated with educating each student $tsCost$, the recruitment cost associated with hiring a health professional $rn(.)Cost$, the costs associated with promoting each health professional into a new role $tn(.)Cost$, and the annual salary $sn(.)Cost$ paid to healthcare workers in each position, the objective function may

then be written as

$$\min \sum_j tsCost(s(.)_j) + rn(.)Cost(n(.)recruited_j) + tn(.)Cost(n(.)promoted_j) + sn(.)Cost(n(.)_j)$$

To obtain the present value of the cost incurred, a discount factor may be added to the objective function calculations.

Finally, the last component of the LP is the set of constraints to be met. For example, it is important to ensure that minimum quality standards are met. This can be expressed in terms of the minimum number of trained health professionals that must be available and willing to work each year ($n(.)min$). Such a constraint can be written as

$$n(.)_j \geq n(.)min \text{ for } 1 \leq j \leq N$$

where $n(.)min$ may be determined from demand-based models or, in the case of hierarchical models, $n(.)min$ may be a function of the number of workers that need to be supervised.

Furthermore, the assumed flow of health professionals through the system should be well modeled; for example, a student can only be in the fourth year of an educational program if the third year of the program has been completed and there exists an intention to continue. Assume that it takes exactly 1 year to complete a level of the program. If we let $s(k)_j$ be the number of students in the k th year of the educational program ($1 \leq k \leq 4$ for programs that last four years) and let $Pcontinuing(k)$ be the probability that a student in the k th year of the educational program continues to the next year of the program, the above-mentioned example may be written as

$$s(4)_j = s(3)_{j-1}Pcontinuing(3) \text{ for } 1 \leq j \leq N$$

where $s(3)_0$ represents the initial number of students in the third year of the program. For the first level of the program, the total number of students will equal the number of students admitted to the first level of the program ($s(1)admitted_j$):

$$s(1)_j = s(1)admitted_j$$

Some healthcare programs admit students who have completed related studies in other fields into higher levels of the educational program. For instance, if students can be admitted into the third year of the program (as is the case with the RN diploma to Baccalaureate programs in nursing), the flow constraint may be written as

$$s(3)_j = s(2)_{j-1}P_{continuing(2)} + s(3)_{admitted_j} \text{ for } 1 \leq j \leq N$$

Similar flow constraints may be written for all other educational levels. In a similar manner, the number of workers at each level l ($1 \leq l \leq M$, where M is the number of workforce levels modeled) will depend on the number of workers in the previous year ($n(l)_{j-1}$), the number of workers promoted to ($n(l)_{promoted_j}$) and from ($n(l+1)_{promoted_j}$) that level, the number of workers recruited at that level ($n(l)_{recruited_j}$), and the attrition from the profession ($P_{retire(l)}$). Assuming that workers can only be promoted to subsequent levels, this constraint may be written as

$$n(l)_j = n(l)_{j-1}(1 - P_{retire(l)}) + n(l)_{promoted_j} + n(l)_{recruited_j} - n(l+1)_{promoted_j} \text{ for } 1 \leq j \leq N \text{ and } 1 \leq l \leq M$$

where $n(0)_{promoted_j}$ is based on the students in the last year of the program who graduate and are able to practice in the profession and $n(M+1)_{promoted_j}$ should equal 0. Moreover, there might be other restrictions that the decision maker might face such as full-time equivalence calculations of workers in the system (as part-time workers are common in some health professions), limitations on the number of professionals that can be recruited, limitations on the workers that can be promoted, and how quickly educational programs can be expanded. The formulations of such constraints are further discussed in Lavieri and Puterman [33].

Implementing the Linear Programming Approach

We developed such a model on an MS-Excel® platform [34] and used the Frontline solver add-on [39] to obtain solutions. While the size of the model can be appreciated from the screenshot provided, the user-friendly interface and the ease of introducing changes to the model's parameters contribute to its appeal and efficacy.

When opening the tool, the decision maker is first taken to the *Model Setup* tab to specify the general characteristics of the model: the ages modeled (from 18 until 65 in our sample model), the number of periods to model (20 periods in our example), and the levels of workforce (4 years of study and 3 levels of workers in our example).

The next step involves identifying the inputs to the model (initial conditions, probabilities, and costs). The key inputs to the model are summarized in Table 1. Not all quantities will have the same impact on the solution. One attractive feature of a linear programming approach is that even if the decision maker encounters limitations in data accessibility—or is unsure of some assumptions—by formulating the problem as an LP, it is possible to determine how much the solution would change if the objective or constraints were changed or if further constraints were added or deleted. The decision maker might thus place greater emphasis on the accurate collection and calculation of those parameters that have the greatest impact on the decision-making process. Table 1 provides general descriptions of inputs and data sources. The choice of inputs is provider specific and dependent on the scenarios that the decision makers will want to examine. Additional elements or inputs can be identified and are only limited by data availability and the assumptions made about the inputs.

On the basis of these inputs, solving the LP determines a minimum cost plan. Even in the large instance described (with 20 periods, 4 years of study and 3 levels of workers, 126 decision variables, and 7497 bookkeeping variables), the solution is

Table 1. Potential Model Inputs

HHR Element	Potential Inputs	Description	Potential Data Sources
Production	Education costs	Annual cost of funding a health professional education program seat	Government, education programs
Production	Age demographics	Current demographics of students	Education programs, accreditation bodies, and regulatory bodies
Production	Probability of continuing education	Fraction of students that complete each year of the education program	Education programs
Supply	Probability of passing licensure examination	Fraction of graduates that pass the licensure examination	Regulatory bodies
Supply	Probability of leaving the province after graduation	Fraction of health professionals that do not remain in the province after graduation	Education programs and regulatory bodies
Supply	Age distribution	Current demographics of health professionals	Employers, regulatory bodies, and census data
Supply	Attrition rates	Annual probability of permanently leaving the workforce in the province	Regulatory bodies and employers
Deployment	FTE	Full-time equivalents (or other similar measure) of each health professional. For example, full-time positions, hours worked, and number of clients seen per week	Employers and government
Deployment	Workforce ratios	Ratios of professionals in one role to another. For example, family to specialist physicians; private versus public employed pharmacists; and staff nurses to managers	Employers, government, and regulatory bodies
Financial costs	Annual salary	Annual salary or wage paid	Employers (including private sector), unions and professional associations, and government
Financial costs	Recruitment and turnover cost	Incentives, orientation, and other recruitment costs incurred per recruited health professional	Employers
Financial costs	Management education cost	Cost of training to promote a health professional to another role such as management or education	Educational institutions and employers
Need/demand	Demand for provider	These inputs will be provider specific and may include number of visits, hospital utilization, and population healthcare needs	Government, employers, and research literature
Need/demand	Projected population		Census data

obtained in seconds on a PC. Information that can be obtained from such a plan constitutes the outputs of the model. Outputs may be tailored to meet the needs of decision makers. Possible outputs include the number of students and health professionals each year in the system, the fraction of recruits from other healthcare systems versus professionals that are new to their positions and key costs incurred.

As mentioned earlier, the richness of this approach relies on its ability to perform “what-if” analyses to assess the impact of potential changes to the assumptions. Examples of scenarios that could be analyzed in this context include

- Retaining health professionals and providing incentives (e.g., modifying $sn(.)Cost$) that aim at decreasing the attrition rate ($Pretire(.)$) from the profession.
- Changing assumptions regarding demand for health professionals ($n(.)min$).
- Addressing the impact that the global shortage of health professionals might have on the entire system.
- Examining changes in skill mix or role changes within a health professional group (which will also impact $n(.)min$).
- Analyzing the impact of budgetary changes.
- Changing the duration of educational programs.

These scenarios provide examples that could be addressed with a linear programming model. We have shown that it is worthwhile to extend temporary leave if that improves staff retention in the long term. Diminishing attrition rates from educational programs played a greater role in our solutions than increasing the number of years a worker stays in the position before he or she retires. Other policy implications obtained from our models are discussed in Refs [34, 36, 37]. The model itself can be adapted to be used nationally, regionally, or at the institutional level. The inputs and outputs must then be adjusted accordingly.

Modeling Considerations

When designing an LP for HHR planning, there are various issues that must be considered. The planner must first decide the level of detail to be modeled: institutional, provincial, national, or for a subspecialty. The level depends on the questions to be answered. For instance, the decision maker might wish to determine how many students to admit each year to educational programs, whether major recruitment policies of professionals from other regions are necessary, and how to meet the need for upper managerial positions on a regional or national level. Such a framework is more strategic than a model designed to aid in operational decisions (such as hiring, training, and scheduling resources) within a hospital or other health organization.

Furthermore, the planning must be done over the long run to ensure that the decisions made are not only appropriate now but also consider future implications. However, deciding over how many periods to solve the problem is another key issue that needs to be considered. A period is the time interval between decision epochs. Including too many periods makes the model more complex (in terms of the data needed as well as the size of the model), while incorporating too few periods might not represent the problem appropriately, and it might not consider the long-term implications of today's decisions. Under certain conditions, a look-ahead policy (obtained by recursively solving the finite-horizon problem) has been proved to be optimal [35]. We suggest using this type of models on a rolling horizon basis; that is using the solutions for the first periods and then solving the model again as new (or more accurate) data become available. Using sensitivity analysis, it is possible to determine how much the solution for the first periods would change given expected changes in future data.

As the availability of health professionals might be affected by age in terms of attrition or full-time equivalency, the model should track not only the number of professionals each year but also the number in each age range. How wide each age range should be will depend on the level of detail needed to make appropriate decisions and the data

availability. Note that not all age ranges need to be the same size.

In the case that there are multiple ways in which all constraints could be satisfied, the objective function can be used to ensure that no more professionals are educated, promoted, and recruited than are needed in the long run. As described in the previous sections, this is accomplished by setting the objective to minimize the total cost incurred. However, other objective functions may also be used based on the outcomes sought by the user.

The linear programming approach described in this article does not come without limitations. While we have discussed the importance of choosing the length of the planning horizon, as results near the end of the horizon may suffer from end of horizon effects, other aspects need to be considered. For instance, this model is designed to answer aggregate level decisions and hence is based on parameter averages. Greater level of detail may be obtained by considering the distributions of the parameters; stochastic optimization and simulation provide two approaches to do this. In addition, we forecasted demand by multiplying population to nurse ratios by population projections prepared by government agencies. We investigated the sensitivity of the demand forecast by choosing current ratios, the lowest Canada wide ratios, and the most desirable targets based on best practice. The decision maker may wish to consider other needs based approaches to estimate demand. Even with those limitations, our linear programming approach provides useful policy insights and suggests where further effort may be placed to collect more detailed data to address the problem at hand.

CONCLUSIONS

We have presented an introduction to the use of linear programming in strategic HHR planning. Moving beyond static, one-time model approaches to ones that incorporate flexible scenarios provides another tool for decision makers to examine HHR decisions. Recognizing the influence of policy decisions

made in one sector on another and being able to simultaneously model changes can support more evidence-informed HHR planning. The decision maker must be aware of the assumptions made in the model formulation. However, the strength of a linear programming model relies on its ability to perform sensitivity analyses. We believe that a linear programming approach can be very useful to decision makers faced with HHR planning problems and that formulating the problem in such a systematic way might be the key to gaining the necessary insights to make such important decisions. The reader is however cautioned that no one approach should be used in isolation when making HHR planning decisions.

INVENTORY INACCURACIES IN SUPPLY CHAINS: HOW CAN RFID IMPROVE THE PERFORMANCE?

YACINE REKIK

Finance and Control Department,
Emlyon Business School, Ecully,
France

INTRODUCTION

Many research workers have alluded to the tremendous payoffs associated with an effective management of operations [1,2]. Companies adopting innovative supply chain management solutions that enhance the value added to customers at a lower cost are improving their competitive advantage. Nowadays, radio-frequency identification (RFID) technology, which is one type of automatic identification and data capture (AIDC) systems currently available, is becoming the basis for such new solutions contributing to a better management of supply chains, in terms of cost reduction and improvement of the customer service level. In most industries, AIDC systems originated with the use of barcode readers, barcode labels, and the universal product code (UPC). In a bar code system, in order to be detected and identified by readers, labels must be positioned precisely. This characteristic, called *line-of-sight positioning requirement*, necessitates human intervention for scanning products and leaves room for errors and inefficiencies. The problem is intensified by the fact that companies rarely have common product codes for specific products or parts [3]. Also, the increasing quantity and variety of information to be managed make the definition of standard transactions for exchanging the gathered data difficult [4]. There is therefore a need for the development of new data capture and product identification systems. Our work is motivated by the recent development of the

RFID technology, which is a system that can potentially perform even better than the bar code system and replace it in the long term [5]. This technology is basically based on the use of wireless RFID tags that carry unique electronic product codes (EPCs) and a set of software components that permit the exchange of data in a supply chain.

Several investigations have attempted to evaluate the benefits of RFID. Most of case-study-type research considers the evaluation of hard (direct) benefits [6]. However, these modeling approaches may not be sufficient for the quantification of some other types of benefits, such as the benefit of having more accurate inventory records.

Atali *et al.* [7] characterize three different kinds of demand streams that result in inventory discrepancy. Some demand streams result in permanent inventory shrinkage (such as theft and damage). Some demand streams are temporary and can be recovered by physical inventory audit and returned to inventory (such as misplacement). The final group of demand stream (such as scanning error) affects only the inventory record and leaves the physical inventory unchanged. A detailed analysis of factors generating errors will be provided later.

The aim of this article is to provide a comprehensive study on the inventory inaccuracy issue and to show the way the RFID technology can improve the performance of supply chains subject to these inaccuracies. The remaining part of this section will be concerned with the main sources causing inventory inaccuracy: we focus on the impact on the performances and briefly detail main investigations performed for each type of source. Then, in the section titled "How to Cope with Inventory Inaccuracy," we provide the different ways that permit us to cope with the inventory inaccuracy issue. For this purpose, we show that RFID technology could be an interesting alternative as proven by many recent investigations. The aim of the section titled "A Framework Enabling Modeling Inaccuracies and the Impact of RFID"

is to present a framework that allows the modeling of an inventory system subject to inaccuracies and to show how we can measure the impact of RFID on such system. Finally, the last section ends the article.

The Inventory Inaccuracy Issue

The standard literature on inventory models has rarely differentiated between the inventory record and the physical inventory. The two have always been considered to be the same, and the main concern was on how, having observed demand and the resulting inventory levels, an inventory manager should determine when and how much to replenish. On the basis of empirical observations, this implicit assumption has been proven wrong. In fact, based on a study done with a leading retailer, Raman [8] reports that out of close to 370,000 Stock-Keeping Unit(SKU) investigated, more than 65% of the inventory records did not match the physical inventory at the store-SKU level. Moreover, 20% of the inventory records differed from the physical stock by six or more items.

A general definition of accuracy includes obtaining the correct value for a measurement at the correct time [9]. According to Iglehart and Morey [10,11], inventory inaccuracy occurs when the system inventory, that is, what, according to the information system (IS), is available, does not match the physical inventory, that is, what is actually available. Various other definitions going in the same sense and measures of inventory accuracy are presented in Refs 12–17. For example, Ernst *et al.* [12] propose using a control chart to monitor the changes in the inventory accuracy. Another definition provided by Bernard [14] considers the percentage (and not the difference) error in the inventory records. Martin and Goodrich [17] define accuracy as the total dollar deviation between the actual dollar value of the inventory and the recorded dollar value of the inventory. As a conclusion of the last provided definitions, we say that an inventory stock is inaccurate when the record stock is not in agreement with the physical stock.

Inventory inaccuracy can be a major obstacle to improvements in firms' performance [18]. While companies have undertaken large

investments to automate and improve their inventory management processes, inventory IS and physical inventory are rarely aligned [8]. Inventory inaccuracy might result from several factors. The aim of this section is to present a comprehensive analysis of the factors generating inventory inaccuracy. On the basis of empirical and qualitative investigations, we try to focus on the order of magnitude of these errors. We also provide the main quantitative investigations for each error type.

Transaction Errors. Transaction errors are unintentional errors occurring during inventory transactions. Some of these transactions happen when counting the inventory, receiving an order, or checking out at the cash register.

Errors when checking out occur if the cash register scans one item twice, rather than each item separately, when a customer is buying two similar (but not identical) items with the same price. This innocuous action by the cash register ensures that the customer pays the correct amount and may even save the customer time as the cash register avoids handling the additional item. However, it generates a discrepancy in the inventory IS. Errors when picking impact inventory records similarly. A warehouse employee can unintentionally ship the wrong quantity of a particular item to a store or even send the wrong item altogether. According to DeHoratius and Raman [11], in an apparel warehouse, it is quite easy for an employee to mistakenly pick a "medium" instead of a "large" garment. Stores typically do not scan merchandise on receipt, allowing such errors to remain invisible. In her PhD dissertation, Sahin [19] provides a comprehensive analysis of inventory systems subject to perturbations in nominal flows. According to the author, the major defects resulting in transaction errors are the following:

- the technical limitations of the bar code system;
- the potential failures stemming from the interaction between inventory operators and the bar code system. Those errors result in (i) errors made

when identifying entities, (ii) errors made when counting, and (iii) errors made when keypunching data.

Concerning the impact of transaction errors, we note that there is some empirical data available in the context of retail stores. Kang and Gershwin [20] report the results of a study conducted by a global retailer in several hundred of its stores. Inventory records were accurate for 51% of SKUs, whereas for 76% of SKUs the deviation between physical inventory and inventory records was within a range of ± 5 units. This means that for close to one in four SKUs, inventory records deviated from physical inventory by six or more units. In another empirical study conducted by DeHoratius and Raman [11], who examined inventory record accuracy at a multibillion dollar retailer, the authors found that the absolute difference between inventory records and physical inventory was on average close to five units. For 15% of SKUs, it was above eight items. This compares with an average target inventory of 14 units per SKU. Average inventory inaccuracy varied considerably by store, with a minimum of 2.4 units per SKU and a maximum of 7.9 units. The same investigation suggests that factors such as higher selling quantity, inventory density, and product variety are associated with higher levels of inventory record inaccuracy.

Among examples of studies that quantify the impact of inventory inaccuracies, the first one is performed by Iglehart and Morey [10], who propose an analytical tool to aid in controlling inventory errors, the objective being to select the type and frequency of counts and to modify the predetermined inventory policy by adding a buffer to compensate for errors so as to minimize the total cost (inventory holding + inspection costs) per unit time. Sandoh and Shimamoto [21] also builds a model that determines the optimal frequency for periodical inventory taking processes within a supermarket, which results from the trade-off between the cost for inventory-taking activities and the cost of investigating the causes of deviations. More recently, the work conducted by K  k and

Shang [18] aims at finding effective inventory replenishment and inspection policies that minimize inventory and inspection costs over a finite horizon. In their framework, the authors represent inventory inaccuracy through random errors that change the physical inventory at the end of each period and errors accumulate until a costly inspection is performed. They propose a near-optimal joint inventory inspection and replenishment heuristic.

Misplacement Errors. Misplacement errors occur when a fraction of the inventory is misplaced; it is not available to meet a customer demand until it is found. According to Chappell [22], there are several sources generating misplacement errors such as (i) consumers picking up products and then putting them down in another location, (ii) clerks not storing products on the correct shelf at the right time, and (iii) clerks losing products in the backroom. From a four-year longitudinal study of 333 stores of a large retailer, Ton and Raman [23] show that increasing product variety and inventory level per product is associated with an increase in misplaced products. The authors also show that increasing misplaced products is associated with a decrease in store sales. According to   amdereli and Swaminathan [24], misplaced inventory is also present in warehouse operations. G.T Interactive, the creator of computer games like Doom II and Driver, suffered from low productivity due to inventory misplacement in the warehouse. Fundamentally what happens in these settings is that the product is misplaced in the supply chain and is unavailable during the sales period but can be retrieved when a cleanup is performed.

Misplaced inventory can be quite large and have a significant impact on the inventory performance. It is reported in Ref. 8 that customers of a "leading retailer" cannot find 16% of the items in the store because of misplacement errors. The consequence is that misplacement errors reduce the profit by 25% for this retailer.

The authors in Ref. 25 model the consequences of random misplacement errors on the retail supply chain by comparing three approaches. In the first approach, the

retailer is unaware of the misplacement and places his orders as if inventory information is perfect. In the second case, the retailer is aware of the errors in his inventory status information, and adjusts his ordering policy accordingly. In the final approach, perfect inventory status information based on RFID technology is assumed. They also provide a critical value of the RFID cost, which makes its deployment cost effective. As an extension of the last investigation, the authors in Ref. 26 consider the impact of misplacement-type errors and the effect of the RFID technology on a decentralized supply chain. In particular, they compare two possible strategies, in which the first deals with the deployment of the RFID technology and the second considers the coordination of the channel by using a modified buy-back contract. Gaukler *et al.* [27] investigate the effects of the RFID technology within the context of the retail supply chain. They build a newsvendor model that takes into account the inefficiency of the replenishment process from the backroom to the shelf in the retail store. Then, based on this model, they examine how the cost of the RFID implementation should be shared among the supply chain actors, and determine coordinating contracts for the RFID-enabled supply chain within a newsvendor framework. Çamdereli and Swaminathan [24] study also the misplacement-type errors in a decentralized supply chain for uniform distributions of demand and error.

Damage and Spoilage. For supermarkets, perishables are the driving force behind the industry's profitability and represent a significant opportunity for improvement, accounting for up to \$200 billion in US sales a year but subjecting firms to losses of up to 15% due to damage and spoilage [28]. Examples of limited lifetime products are drugs and food products. In retail stores, customers can cause damages to products, thereby making them unavailable for sales. Some examples are, tearing a package to try on the contained cloth item, wearing down a shoe by trying it on and walking, erasing software on computers on demonstration, spilling food on clothes, and scratching a car during a test drive [29]. These damages may not be detected by the

inventory manager and as a consequence would cause inventory inaccuracy.

According to Sahin [19], items reach their limit lifetime during storage because of the following:

- Errors when forecasting the customer demand, which may lead to an overestimation of this demand and as consequence a substantial quantity of products not being sold.
- The inability to track accurately the location, condition, and the age of products stored within a facility.

An industry survey performed by the Joint Industry Unsalables Steering Committee [30] provides data on the level of unsalables in the US retail industry. According to the survey results, which are based on responses from over 60 manufacturers and retailers, the cost of unsalable food and grocery products amount to 1% of sales in the United States. Damage is the biggest cause of unsalables with 63% of all unsalables, followed by expired (16%) and discontinued items (12%). The rate of unsalable products can differ by product category: frozen products, for example, reported an unsalable rate of 0.9%, whereas the rate for refrigerated products was 1.7%. Unsalable rates for health and beauty care and general merchandise had even higher unsalable rates (1.9 and 2.2%, respectively), which was attributed to frequent new product introductions, shifts in fashion component, seasonality, and short shelf-life.

Theft. Inventory theft is defined as a combination of employee theft, shoplifting, internal and external theft, vendor fraud, and administrative error. The Efficient Consumer Response (ECR)¹ Europe project on shrinkage subsequently analyzed the causes of stock loss and proposed a systematic and collaborative approach to reducing the phenomenon throughout the supply chain. ECR defines "shrinkage" as the process errors, deceptions, and internal and external thefts. According

¹<http://www.ecr.org/>

to Beck [31], some specific types of internal theft include the following:

- staff stealing goods by either hiding them in their bags or intentionally placing them outside the building for later collection;
- collusion occurring when a staff member collaborates with a customer to steal products. During such an incident, the staff member may not scan the item, or the security personnel may intentionally ignore the offense as it occurs;
- grazing occurring when items stored in the warehouse are consumed by the warehouse staff.

The results of the research carried by ECR Europe have shown that the scale of shrinkage in the fast-moving consumer goods sector is estimated to be €24 billion in 2003 (465 million euros is lost irreparably within the fast-moving consumer goods turnover weekly), which is 2.41% of the whole turnover value of the sector. The process errors present 27% of the whole shrinkage value, 7% deceptions, 28% internal thefts, and 38% external thefts.

On the basis of survey data, internal and external theft, administrative errors, and vendor fraud accounted for an estimated 1.8% of sales in the US retail industry in 2001, costing US retailers \$33 billion [32]. For US supermarkets, the National Supermarket Research Group (NSRG) survey [33] estimates that internal and external theft, receiving errors, damage, accounting errors, and retail pricing errors amount to 2.3% of sales. These figures only take into account the item value, but not any process-related costs (e.g., for handling of damaged items). Kang and Gershwin [20] use simulation to analyze the consequence of inventory inaccuracy. They show that even small undetected losses can lead to important stockouts. They also propose several ways to tackle this problem, including the deployment of RFID technology. The authors in Ref. 34 use also simulation to show the consequences of inventory inaccuracy in a three-stage supply chain. Considering misplaced-type errors, the authors in Ref. 25 show analytically the impact of errors on the inventory decision

strategies and derive a threshold cost value at which RFID deployment would become cost effective. Extending the model of Rekik *et al.* [25,26] consider the case of a decentralized supply chain with one manufacturer and one retailer whose inventory is subject to inaccuracies. They develop the optimal ordering strategies under the centralized and the decentralized scenarios and study the impact of the RFID deployment on such supply chains. Heese [35] studies a supply chain consisting of a Stackelberg leader manufacturer and a retailer with inventory inaccuracy and random demand. Using specific distribution functions, he derives the threshold value of tag cost in order for a firm to adopt RFID. More recently, Rekik *et al.* [36] consider a finite horizon, single-product periodic review store inventory in which inventory records are inaccurate due to theft errors. They analyze the problem of theft in the store by optimizing the holding costs under a service level constraint, and analyze the impact of theft errors and the value of the RFID technology on the inventory system.

Supply Errors: Product Quality, Yield, and Supply Process. When the product quality is low, or a production process has a low yield, or a supply process is unreliable, the physical inventory may not be known and as a consequence may be different from the inventory in the IS [37–39]. Products that are not conforming to quality standards can also make the inventory inaccurate. According to Bensoussan [29], receipts are usually added to the inventory without a full inspection process. The consequence is that the IS may consist of both nondefective products and defective products which are not available for sale.

HOW TO COPE WITH INVENTORY INACCURACY

To cope with inventory inaccuracy, different compensation methods can be used. The analysis conducted by many investigations [19,20,40,41] agreed that (i) making decisions by considering the inventory inaccuracy may be applied to tackle the problem of inventory inaccuracy and (ii) RFID technology

may help to track items through the supply chain. In addition to reducing the inventory inaccuracy, this technology may also help to eliminate the reasons of inventory inaccuracy such as theft.

For the specific case of misplacement errors, inventory managers may apply other methods to tackle the problem of misplaced inventory. For example, in some apparel departments of retailers, there are signs informing customers not to return the product to their original location if they decide not to buy the product after trying it. Some libraries cope with the misplacement problem by putting signs that tell the customers not to reshelve the books after use, while others have designated spaces for returning books taken off the shelf [24].

The analysis conducted by Kang and Gershwin [20] examines various other techniques that inventory managers can use to compensate for the inventory record errors. According to the authors, the compensation techniques can be summarized in the following three points:

- *Verifying Manually the Inventory.* The inventory manager can choose the items in the facility in order to perform a manual, periodic counting. The frequency of counting may depend on various elements, such as the availability of labor and the product characteristics, including the profit margin, sales velocity, and whether the products are highly prone to errors.
- *Performing a Manual Reset of the Inventory Record.* This technique is used if a direct measurement of the physical inventory is not available, and inventory managers can gather and monitor the available data and search for any patterns that may be indicative of the presence of serious inventory error.
- *Performing a Constant Decrement of the Inventory Record.* This technique is performed if the inventory manager is aware of the presence of errors and also knows their stochastic distributions. The inventory manager may decrement the inventory record by the average of the error in each period.

Since the physical value of the error realization at each period is unknown, performing this constant decrement will still not eliminate the error in the inventory record. However, over time, this corrective action can be expected to perform better than leaving the inventory record unadjusted.

In her PhD dissertation, Sahin [19] proposes a set of actions aiming to eliminate errors. These actions can be summarized in the following points:

- reengineering the physical organization of the facility;
- using a new product identification technology that reduces scanning errors;
- using a technology that enables the reduction of theft in the facility;
- using a technology to accurately track the products' sell-by dates;
- performing double receiving and shipment processes;
- improving the actual processes in the facility;
- performing benchmarking analysis and developing personnel awareness building actions that focus on the operational weaknesses.

DeHoratius *et al.* [41] suggest two more ways in which an inventory manager may respond to the inventory inaccuracy problem:

- *Prevention.* Reduce or eliminate the root causes of inventory record inaccuracy through the implementation and execution of process improvement.
- *Correction.* Identify and correct existing inventory record discrepancies through auditing policies.

A FRAMEWORK ENABLING TO MODEL INACCURACIES AND THE IMPACT OF RFID

How to Model Inventory Inaccuracies

A typical supply chain may include three main entities: the manufacturer, the warehouse, and retailers. The manufacturer

produces products, the retailers are the agents selling products to the final customers. Between the manufacturer and the retailers, there may exist a warehouse that acts as an intermediate element that buys products from the manufacturer and resells them to the retailers.

From an inventory control point a view, satisfying customer demands may be different within the retail store and the warehouse. For this reason, two structures may exist:

- *Structure A.* This structure focuses on the retail store context (Fig. 1). The end customers are physically present in the retail store and their demands are handled by the physical on-shelf inventory. The IS does not play a major role in this structure. This structure of the supply chain can be modeled as illustrated in Fig. 2.
- *Structure B.* This structure focuses on the warehouse context (Fig. 3). Customers are not physically present in

the warehouse, and demand satisfaction is met on the basis of the inventory level shown in the IS. On the basis of the demand it receives, the warehouse observes its IS stock and makes a commitment. The commitment is later satisfied depending on the physical available stock. The structure of this supply chain can be modeled as illustrated in Fig. 4.

In the presence of inaccuracies, the two structures do not behave in the same way from an inventory control point of view. We argue that the main difference between the two structures concerns the commitment made by the warehouse under structure B. In structure A, no commitment is made by the retailer since the end customers are physically present in the store.

Remark 1. Note that Internet retailer inventory system can be modeled as structure B since decisions concerning demand satisfaction are based on the IS inventory.

Figure 1. Structure A: the retailer supply chain.

Figure 2. Modeling of structure A.

Figure 3. Supply chain B: the warehouse supply chain.

Remark 2. From an inventory control point of view, structure A can be considered as a particular case of structure B, where the available-for-sale quantity in structure A corresponds to Q_{IS} of structure B, assuming that $Q_{IS} \leq Q_{PH}$.

Under structure B, one can consider the following sequence of events: Before the start of the selling season, the warehouse manager orders a quantity from the manufacturer. This quantity is established based on forecast information available to the inventory manager regarding the future demand. The warehouse receives the goods and stores them. Just before the start of the selling season, the inventory manager receives orders from the customers. He compares the cumulative order from all the customers to the quantity seen in the IS. If the cumulative order is less than the IS quantity Q_{IS} , he accepts all the orders. Otherwise, he only accepts orders summing up to Q_{IS} . Later on, the products are shipped from the warehouse and delivered to the customers. All the orders that the inventory manager has committed himself to

should be satisfied, except in the case where the physical inventory is not able to satisfy the committed quantity. Unsatisfied demand during the commitment and unsatisfied commitment are lost since there is no opportunity for replenishment during the selling season.

The inventory manager's decision is to determine the best quantity to order from the supply system before the selling season to satisfy customer's aggregate demand. He faces three risks: (i) risk of having unsold products at the end of the selling season; (ii) risk of shortage; and (iii) risk of not being able to deliver the quantity that he has made a commitment for. Within this framework, the inventory manager faces three types of costs:

- the unit overage cost due to products unsold at the end of the selling season;
- the first type of unit underage cost due to orders rejected by the inventory manager during the commitment;
- the second type of unit underage cost due to orders initially accepted by

Figure 4. Modeling of supply chain B.

the inventory manager but finally not totally delivered to the customers.

We note that the second type underage cost is the parameter that characterizes the warehouse context. In a retail context, this cost does not exist since the customers are physically present at the store: if the product is not available, the demand is lost, otherwise it is satisfied immediately. The second type underage cost occurs when the customer demand is related to the IS inventory.

To model the impact of inaccuracy errors on the performance of the inventory system, it is important to characterize the error type. In fact, in a general setting, if we let Q the quantity ordered from the supply process, the physical and the IS inventory can respectively be written as follows: $Q_{PH} = \gamma_{PH}Q + \epsilon_{PH}$ and $Q_{IS} = \gamma_{IS}Q + \epsilon_{IS}$, where the couple of random variables $(\gamma_{PH}, \epsilon_{PH})$ $(\gamma_{IS}, \epsilon_{IS})$ characterizes errors on the physical inventory level (IS inventory level). From this general setting, which is called the *mixed error setting*, one can distinguish two particular cases:

- the additive error setting: in this case, $Q_i = Q + \epsilon_i$ where $i \in [PH, IS]$;
- the multiplicative error setting: in this case, $Q_i = \gamma_i Q$ where $i \in [PH, IS]$.

Second, it is also important to discuss how an inventory system subject to inaccuracy problems can be managed. In the presence of errors, one should distinguish between two situations depending on whether or not the inventory manager is aware of the existence of errors. The case where the inventory manager is unaware or simply ignores errors will be referred to as *Situation 1* in the rest of this article. The case where the inventory manager is aware of errors occurring in the inventory system will be referred to as *Situation 2*. For this latter Situation, one can also distinguish between two cases based on the information the inventory manager has about the error parameters. The first case occurs when the inventory manager has statistical information about the error parameter (such as a mean or the distribution of the error). The second case occurs when he has exact

information on the realization of the error. The difference between the two cases makes sense especially in a multi-period framework.

Concerning Situation 2, we notice that an estimation of the error parameters can be realized on the basis of statistical sampling methods as reported by Pergamalis [42], who proposes a methodology for measuring the store's inventory accuracy.

In contrast to Situation 2, Situation 1 is easier to model and optimize. In fact, in Situation 1, the inventory manager acts as if there were no errors. So, his ordering decisions or his replenishment policy coincides simply with the ordering quantity or the replenishment policy of the model without errors.

RFID as a Lever to Tackle the Inaccuracy Problem

RFID technology is a wireless technology that includes RFID tags and readers often linked to an IS through a computer. A tag is basically an antenna, which may be active or passive. An active tag is powered by a battery, while a passive one is not. This affects the performance and price. Because of its characteristics, RFID tags may be read without visual or physical contact. To facilitate physical distribution and inventory management, tags are attached to packaging or unit loads, for instance, transport packaging, pallets, or containers.

RFID technology is developing at a rapid pace, offering companies the opportunity to improve supply chain visibility. In fact, the number of RFID applications in supply chains is increasing steadily, which is indicated by the escalating level of investment in this technology. The Aberdeen Group [43] surveyed over 600 companies using RFID in the last 12 months. According to this study, the average manufacturer's annual RFID budget has grown rapidly, from \$50,000–75,000 in 2006 to \$100,000–\$200,000 in 2007. The study shows that the investments already made greatly improved cycle time, on-time delivery, safety stock, and changeover time.

Several authors highlight the opportunities presented by RFID technology. In the physical distribution field, Jim Wu and

Chen [44] use a simulation study to predict operational efficiency in a distribution center. Thanks to a perfect RFID system (100% read rate), the authors show an inventory reduction of 15%, lowered space use rate of 15%, and elimination of out-of-stock items. The authors in Holmqvist and Stefansson [45] study a mobile RFID system designed to manage arrival inspection and loading of containers. They find both time savings in arrival inspection and lead time reduction in loading, except when there are only a small number of consignments per container. In another study, Jarugumilli and Grasman [46] use invented data to model a vendor-managed inventory (VMI): for an excellent review about VMI systems, the reader is referred to the article titled **Vendor-Managed Inventory** in this encyclopedia (by Michael J. Fry) setting with RFID tags applied to the goods. In Ref. 47, the authors propose a logistics IS to simplify the distribution process with the help of RFID technology. A case study is discussed in applying the proposed IS to solve distribution management problems of a medium-sized logistics service company. By using this RFID-enabled system, the authors show that the overall distribution performance of the company is greatly improved.

On the inventory control side, as stated in the section titled “Introduction,” many recent investigations concerned with inventory inaccuracy issues are motivated by RFID technology and its impact on supply chain performance. Indeed, RFID deployment contributes to the elimination of the sources of inaccuracies through the supply chain:

- Errors resulting from the unreliability of the supply system can be detected thanks to the counting performed when receiving orders. RFID can reduce the errors in receiving via the RFID-enabled process referred to as *electronic proof-of-delivery* (or ePod) [48]. With barcode, mistakes are made by misidentifying the quantity and type of product.
- For food and perishable products, RFID can
 - Facilitate first-in-first-out (FIFO) and pricing management
 - Facilitate the tracking and maintenance of temperature conditions supporting the integrity of the cold chain for some food products
 - Allow getting more accurate information about demand and supply forecasts. Accurate and timely information about stock levels, sales throughput, and production data allow reengineering the overall business. Minimizing buffer and obsolescent stock will lead to lower inventory. Products can be brought closer to the market in the form of mini stocks, once the visibility over those can be guaranteed. Combining product flows from different sources on their way to the receiver becomes faster and more efficient. Overall, this will lead to increased product availability and as such increased sales, which can be even more accelerated by retail applications like automatic cross-selling or product information displays.
- Inaccuracies resulting from shrinkage errors can be reduced by discouraging thieves and by facilitating the location of quantities and timings of theft losses across the supply chain. Loss prevention during transport between sending and receiving parties or even within sites can be achieved by increased transparency and real-time visibility over the goods flow. Basically, the level of tagging (pallet, case, or item) and the frequency of read events determine the degree of loss prevention.
- Products subject to misplacement errors can be detected by deploying RFID readers within shelves and in the backroom.
- Shipping accuracy can be improved. Distribution centers and manufacturers often make mistakes by loading product on the wrong truck. With RFID, the system can send an alert (visible, audible, etc.) to the person loading the truck that a mistake has been made. This alert could save a company money

Figure 5. Situations permitting management of the system.

from shipping and reshipping the same items as well as enhance inventory control.

The decision to invest in RFID technology will depend on the trade-off between the cost associated with the deployment of the technology and the savings resulting from investment. Taking into account the variable² costs associated with RFID, that is, the RFID tag cost embedded in each product, we are able to model the RFID-enabled situation. We note that RFID can bring two benefits for the inventory warehouse as follows:

- The visibility provided by this technology. Theoretically, RFID enables tracking and tracing of items in stock and in the pipeline, thereby creating complete inventory visibility, leading to an accurate account of inventory discrepancy. In such cases, the inventory problem under study is nothing but the basic random yield problem.
- The prevention or reduction of the magnitude of some sources of inventory inaccuracy by RFID. In the case of theft errors, by being able to distinguish customer demand and other kinds of demand (theft for example), the inventory manager can act to prevent or discourage the sources of this latter demand.

The RFID-enabled problem, referred to as *Situation 3*, is also a basic inventory problem where the unit purchase (production) cost of the product includes the RFID tag cost.

To summarize, the Fig. 5 presents the different situation that allow modeling of the

impact of inventory inaccuracies and the benefit pertaining to the deployment of the RFID technology.

Comparing Situations 1 and 2 permits getting insights on the benefit of obtaining information about the errors and establishing a better inventory policy taking into account the inaccuracy issue. Comparing Situations 2 and 3 also permits getting insights into the real benefit of RFID and, in particular, answering the key questions:

- Is RFID deployment an economically feasible solution for the warehouse manager?
- If yes, under which tag price is RFID cost effective?

CONCLUSION

Our major focus in this article was to provide a comprehensive study on inventory inaccuracy and the way RFID technology can tackle this issue. We listed the main sources of errors with a focus on their impacts on the supply chain performances and briefly detailed the main research investigations in this field. We proposed a conceptual framework that permits modeling of the inaccuracy errors and the way RFID can contribute. In fact, three modeling situations show the impact of a better inventory policy, taking into account error distribution and the impact of RFID deployment.

INVENTORY RECORD INACCURACY IN RETAIL SUPPLY CHAINS

NICOLE DEHORATIUS
Zaragoza Logistics Center,
University of Portland

INTRODUCTION

Inventory record inaccuracy (IRI) is a substantial problem in retail supply chains. Retailers rely on automated decision-support tools that use recorded inventory quantities to replenish store shelves, plan product assortments, and forecast demand. In the presence of IRI, these decision-support tools generate suboptimal solutions and ultimately fail to prevent the very problems they were designed to avoid, namely stockouts and excess inventory.

IRI can compromise automated decision-support tools in several ways. IRI may cause an automated replenishment system to order when ordering is unnecessary or fail to order when it should. “Freezing” of the automatic replenishment system, a scenario in which the retailer has no items on the shelf but a sufficiently positive inventory record so as not to trigger a replenishment order, results in a physical stockout [1]. This stockout persists until the retailer identifies the problem and intervenes by replenishing the inventory and correcting the inventory record. Retailers unable to meet consumer demand due to a stockout run the risk of losing not only the sale of that item but quite possibly the consumer’s entire bundle of goods and perhaps even the consumer’s lifetime purchases should the consumer defect to a competing retailer [2].

IRI may also cause an automated demand forecasting system to misestimate true demand. Take, for example, a demand forecasting system designed to forecast future demand for a particular item in the store. If the inventory record for this item

is incorrectly recorded as positive when the item is actually out of stock on the store floor, the demand forecasting system will observe no sales and may incorrectly attribute this lack of sales to a reduction in consumer demand. The demand forecasting system may lower the recommended stocking quantity for this item as a result. Not only are customers unable to find the product on the shelf today due to the stockout but this reduction in the demand forecast makes it less likely for customer demand to be met in the future. Even after this retailer restocks its shelf, the adjusted demand forecast has reduced the target stocking quantity of this item, ensuring that the impact of today’s IRI persists into the future.

In the sections that follow, we document the extent of the IRI problem in retailing and identify several solutions proposed by operations management researchers. We also describe how discrepancies between the actual and recorded inventory quantity arise within stores, highlighting the role that retail replenishment processes play in generating such discrepancies. In particular, we identify how a single process failure in the distribution center (DC) can generate an inventory discrepancy that cascades across product categories and even across stores. We conclude with a discussion on future research opportunities on this topic, which we believe merits the attention of practitioners and academics alike.

EXTENT OF THE IRI PROBLEM

Recent research finds IRI to be both pervasive and substantial in magnitude in retail supply chains. DeHoratius and Raman [3] find inaccuracies in 65% of the records supporting 37 stores of a leading retailer. Similarly, Kang and Gershwin [1] note inaccuracies in 51% of the inventory records among stores of a different retail firm. Both studies find that the magnitude of IRI differs from store to store and DeHoratius and Raman [3] attribute

these differences to store-specific characteristics such as product variety, defined as the number of unique items in a store,¹ inventory density, defined as the total inventory quantity divided by the retail selling area, and audit frequency, defined as the time between storewide inventory audits. Research conducted in contexts other than retailing finds varying levels of IRI in government supply depots [4,5], pharmaceutical warehouses [6], hospitals [7], and DCs [8,9].²

Several studies explore the financial consequences of IRI in retailing. Kang and Gershwin [1], Fleisch and Tellkamp [11], and Waller *et al.* [12] show that even small discrepancies can lead to substantial lost sales, missed service level targets, and suboptimal retail performance. DeHoratius and Raman [3] estimate the lost revenue caused by IRI to be 1.1% of sales. Raman *et al.* [13] find lost sales due to misplaced inventory reduces profits by 25%. Rather than forgo sales, retailers may choose to carry additional inventory to buffer against the added uncertainty caused by IRI. DeHoratius *et al.* [14] estimate that retailer will incur 20% more inventory holding costs, on average, in order to achieve the same service level as a retailer who attempts to mitigate the IRI problem through other means.

IRI can also negatively impact retail partners (distributors and manufacturers) and undermine the performance of collaborative planning forecasting and replenishment (CPFR) and vendor managed inventory (VMI) initiatives. Angulo *et al.* [15] find IRI significantly impacts vendor performance measures such as fill rate. Sari [16], in measuring the total supply chain inventory cost and retailer's customer service level, finds the impact of IRI on retail supply chains utilizing CPFR and VMI depends on how tightly coupled vendors and retailers are within the supply chain. Camdereli and Swaminathan [17], by deriving the

optimal inventory policy for a retailer with a known proportion of misplaced inventory, show that changes in the proportion of misplaced products impact channel partners differently, making channel coordination more of a challenge.

Several mechanisms for mitigating the negative consequences of IRI exist. In the section that follows, we provide a description of several proposed solution for IRI. We also classify each of these solutions into one of three categories (prevention, correction, or integration) identified by DeHoratius *et al.* [14]. Evidence that the problem of IRI is substantial both operationally and financially and that its impact is not isolated to single stores or even stores within a single chain but rather permeates across firm boundaries within a retail supply chain motivates much of this work.

RECOMMENDED SOLUTIONS TO IRI

IRI is not a problem new to operations researchers. Over the course of the last few decades, researchers have been offering solutions to IRI in numerous contexts. DeHoratius *et al.* [14] identify three categories of solutions typically used to address IRI problems in retailing as follows:

1. *Integration.* Use inventory planning and decision tools robust enough to account for the presence of record inaccuracy;
2. *Correction.* Identify and correct existing inventory record discrepancies through auditing policies;
3. *Prevention.* Reduce or eliminate the root causes of IRI through the implementation and execution of process improvement.

We discuss each category in turn.

Integration

Among the first researchers to address the problem of IRI, Rinehart [4] argues that discrepancies between recorded and actual inventory quantities prevent firms from taking advantage of existing inventory control

¹This study operationalizes product variety in several different ways including the number of unique merchandise categories in a given store.

²See DeHoratius and Ton [10] for a full list of IRI problems in other contexts.

levels of inventory in the presence of IRI may actually be able to learn about their true inventory position. This learning, learning that reduces the uncertainty surrounding the retailer's physical inventory position, provides a retailer with distinct advantages when it comes to making future inventory decisions.

Correction

Prevention

Gaukler *et al.* [28] examine the role RFID plays in improving product availability by reducing the likelihood of in-store, shelf-replenishment process failures. Moreover, Gaukler *et al.* [29] explore the differential benefit RFID technology has among channel members and offer suggestions for improved channel coordination in the presence of RFID. Uçkun *et al.* [30] identify the factors

driving the RFID investment decision among channel partners. These factors include fixed costs, demand variance, and the retailer's profit margin. Focusing on channel partners engaged in VMI, Szmerekovsky and Zhang [31] compare supply chain performance with and without the use of RFID to improve replenishment efficiency.

Prevention, however, requires researchers to understand the root cause of IRI. Discrepancies between recorded and actual inventory quantities arise in numerous ways as actual quantities physically move through the retail supply chain and recorded quantities are automatically updated by the retailer's inventory tracking systems. DeHoratius and Raman [3] identify several sources of IRI including replenishment errors, employee and customer theft, imperfect inventory audits, and incorrect recording of sales and returns. In the section that follows, we focus primarily on replenishment errors and provide an in-depth look at the types of problems that can arise.

RETAIL REPLENISHMENT PROCESSES

Replenishment errors, as the following example reveals, warrant additional attention. Raman *et al.* [13] describe an experimental audit whereby executives of one retail chain, unbeknownst to its store and DC managers, decide to audit a store

before it was opened for business but after it had been stocked. This audit revealed that 29% of its records were incorrect—meaning for 29% of the SKUs in this store of nearly 10,000 SKUs, the on-hand quantity did not match the actual quantity present in the store. This level of IRI could not be explained by customer theft, mis-scanning at the register, poor returns procedures, or untracked interstore transfers, activities often cited as contributing to record inaccuracy, as the store was not yet operational. Instead, this level of inaccuracy can only be attributed to errors in the delivery of product from this retailer's own DC to this store. The accumulation of errors, namely the failure of employees to correctly execute specific processes, within a retail DC can ultimately create record inaccuracies at the retail stores if such errors go unnoticed.

The replenishment of store inventory from retail DCs typically involves five main phases. Figure 1 depicts these phases beginning with the arrival of merchandise from manufacturers and distributors and concluding with the loading of trucks scheduled for store deliveries. These phases include the following:

- *Receiving.* The process of unloading in-bound trucks and verifying actual arrivals against advanced shipping notices and/or purchase orders. This is the entry point of goods from the

Figure 1. Retail Replenishment Process.

manufacturer or distributor into the DC.

- *Storage and Put-Away.* The process of putting the goods into the place where they will be stored until it is time for them to be picked, Casepack locations and breakpack locations are among the two most common categories of storage types. Casepack locations are for items that are shipped in casepack quantities. Breakpack locations are for items that are shipped in quantities smaller than the casepack size.
- *Picking.* The selection of goods from storage locations. The item and quantity to be picked is itemized on a packing list. The packing list identifies all those items needing to be shipped from the DC to the retail store in a specific time period.
- *Quality control.* The examination and audit of orders picked prior to store shipment.
- *Loading and Store Receiving.* The process of preparing the goods to be shipped as well as packing the truck destined to the retail store. This is the exit point for the goods held within the DC.

Essentially, DC employees receive inventory from manufacturers and distributors, place it in one or more of several storage areas, and ultimately prepare it to be shipped to stores. Shipments from these DCs to retail stores can occur as often as daily or as infrequently as monthly, depending on the demand characteristics of the store. We will explore each of these phases in detail below.

Receiving

The receiving process marks the point of entry for inventory arriving into the DC from the manufacturer. A retailer receives goods through dock doors located in one distinct area of the warehouse that is separate from the outbound shipping area. Receivers are stationed at the dock doors and are tasked to manually examine the in-bound cases, or boxes, stacked onto pallets as the pallets are unloaded from the truck. Their main function is to check for discrepancies between

actual receipts and packing lists, and actual receipts from purchase orders.³ Discrepancies do arise with some frequency [32]. DeHoratius [33] found 8% of the purchase orders arrive in error and require additional work prior to acceptance into the DC.

To conduct this check, receivers sometimes break down “mixed” pallets, pallets that contain cases of different SKUs, and load individual cases onto separate pallets—one for each SKU. This enables them to certify that the expected number of cases for each SKU has arrived. A few cases are randomly opened in order for receivers to check for damage, verify that the appropriate quantity within a case has been received, and determine whether any unauthorized substitutions⁴ have occurred. Once receivers are satisfied with this shipment’s accuracy and completeness, they generate a series of bar code labels, or license plates, to affix to the front of each pallet. These license plates direct the pallet to the appropriate storage location within the DC and will be read by the stock keeper during the next stage of the distribution process.

The DC’s inventory records are updated to reflect these newly received items in the following way. Using a hand-held scanning device, receivers scan the bar code located on the case and then enter the number of cases of that particular SKU they have counted. The warehouse management system contains information regarding the expected number of individual items per case. Thus, this case count triggers an item-level inventory record update in the warehouse management system.

Storage and Put-Away

Once received, these pallets are stacked in a holding zone or staging area on the receiving

³Some companies check receipts against invoices or even against advance shipping notices. The important point is that there is some process whereby what actually arrives at the dock can be verified with what was expected to arrive.

⁴Unauthorized substitution is when a vendor, either mistakenly or knowingly, ships a substitute item for the item ordered.

floor of the DC until stock keepers can put them away into designated storage areas. The put-away process begins with the stock keeper scanning the license plate generated during the receiving process and ends with the stock keeper bringing the goods to their assigned location within one of three primary storage areas. The three primary storage areas include (i) the case-pack area, (ii) the break-pack area, and (iii) the bulk or flow-through area. As their names indicate, each storage area holds goods that will be shipped to stores in different formats. For example, the case-pack area stores goods that will be shipped to stores in full cases, the boxed quantity provided by the manufacturer. The break-pack area stores cases that will be opened, or broken, to allow the hand-picking of individual items to be shipped to stores. As described in the next section, pickers pack select quantities of individual items into totes containing a variety of different items. These totes will make their way to the outbound shipping lanes by way of conveyor belt. The flow-through area is essentially temporary storage for cross-docked products—products that will be shipped to stores within 24 hours of receipt.

Pallets or cases of the same SKU may be stored in multiple locations, each with a unique location number, either out of necessity (the assigned area for a particular SKU is not large enough for all items to be colocated) or by plan. For example, one store may receive case quantities of a particular SKU, and thus this SKU can be found in the case-pack area, while another receives less than case quantities, and thus this SKU can also be found in the break-pack area.

Picking

Picking is the step by which inventory is selected and moved from these storage areas to the shipping lanes dedicated to trucks delivering to particular stores. Pickers are responsible for selecting items from storage areas that will be shipped to stores. Pickers receive “pick lists” to guide their selection process. These pick lists represent the store’s replenishment order as they designate which items and quantity of items

should be selected from DC shelves. The list includes the SKU number, a short description of the product, a product location identifier, and a quantity indicating the exact amount that it to be selected. If a picker is selecting less than case quantities, these items will be selected from shelves that contain open cartons of items from which pickers will select small quantities and the selected items will be placed into a tote that will eventually be sent via a conveyor belt to the appropriate shipping lane for that particular store. For pickers selecting cases, these cases may be sent down the conveyor to the store’s shipping lane. A bar code is placed on each tote and case by the picker to identify which store’s order is contained in that tote or which store’s order is associated with that case.

Quality Control

After being selected and placed onto the conveyor belt, all items pass through quality control prior to being packed and shipped. Quality control often involves a comprehensive automated and a random manual process. The automated process entails a scanner located near the end of the conveyor belt that reads each bar code placed on the outbound totes and cases. This scan is meant to verify the completeness of a store’s order. DC managers turn to the results of this scan to justify that a tote or case destined for a particular store has actually left the facility. In addition, there is a manual audit to supplement this automated process. The manual audit is meant to verify the correctness of the order by actually matching items en route to a store to that store’s pick list for a randomly selected number of outbound cases and totes. Quality control personnel initial the bar code to indicate the order has been checked before allowing the tote or case to proceed to the shipping lanes.⁵

⁵Some retailers require manufacturers to allocate a certain number of cases to specific stores. The manufacturer would then label the cases appropriately (e.g., with a store number) and these cases can then be shipped to stores upon their receipt at the DC. Similarly, retailers may label cases with store specific details upon their receipt and ship them out to stores the same day.

Loading and Store Receiving

Once the totes and cases have cleared quality control, they are automatically sorted by the conveyor belt system into different staging areas near store-specific shipping lanes where the cases and totes are packed and loaded for transport to the retail stores. Packers place the totes and cases onto pallets, shrink-wrap the pallets, and then place the pallet into the appropriate shipping lane. Dockworkers then load the pallets onto the designated truck. Once the truck is loaded, the door is closed and sealed and the items are now en route to the retail store.

At this stage, the DC's and the store's inventory records are updated to reflect this change in inventory ownership. The store's inventory is automatically updated to reflect the receipt of its replenishment order. The DC's inventory is automatically depleted by the amount of items it shipped to fill each of the order's from its affiliated stores. If the DC was unable to completely fill the store order (e.g., the DC was out of stock of a popular item), that item would need to be manually "scratched" or removed from the order to prevent the corruption of both DC and store inventory records.

Most retailers do not scan each individual item into its store inventory but rather rely on the automatic inventory update. The receiving process at the backdoor of a store entails a check to see whether the expected number of pallets or cases has arrived and, perhaps, a partial count of high value items. Some retail policies discourage store employees from conducting a detailed check of store receipts, as only discrepancies above a certain threshold dollar amount qualify a store for possible credit from the DC.

EXECUTION FAILURES IN THE RETAIL REPLENISHMENT PROCESS

The retailer's objective is to ensure that the delivery truck destined for a particular store is filled with the right product in the right quantity as defined by the replenishment order. The expectation is that each replenishment order will be filled accurately and

completely. However, the replenishment process described above may not always proceed as planned. There are numerous opportunities for mistakes to occur (See Fig. 2), each of which may have different consequences for the accuracy of store inventory records. This section describes and categorizes the errors that may occur in the replenishment of store inventory from the retailer's DC.

Sorting Integrity

During the receiving process, when receivers are breaking down mixed pallets and sorting cases in an effort to place like products onto the same pallet, it is possible for receivers to mistakenly misplace a case onto a pallet of dissimilar SKUs. It is very difficult to differentiate cases containing different SKUs from one another quickly since manufacturers' packaging is nearly identical and the markings on bar codes can be difficult to read without the assistance of a hand-held scanner.

In this instance, when a case is misplaced onto a pallet of dissimilar SKUs during the receiving process, this case will be routed to the wrong storage location and, if not discovered, will result in a picker selecting the wrong product and the store receiving the wrong product. Consequently, the store that was supposed to receive a case of SKU A actually receives a case of SKU B and two inventory records are now corrupt. The store's inventory records will be updated to reflect the receipt of an entire case of SKU A but none has been received. Instead, it has received an entire case of SKU B while the recorded quantity of SKU B at that store remains unchanged.

It is difficult to correct a sorting error because it occurs so early in the distribution process. Once a case is on the wrong pallet, the case is sent to storage on this pallet. If the entire pallet gets shipped to the store, the error will be present in the store. The store inventory will be updated with 10 cases of item A when, in reality, 9 cases of item A and 1 case of item B were received. Such errors are difficult to identify without an audit.

Another difficult problem to identify is when a tote or case does not make it to the correct shipping lane from the conveyor belt. This happens when the scanner is unable

Figure 2. Sample of Errors that Arise During the Retail Distribution Process.

to read the bar code placed on the case or tote by the picker. In this instance, the scanner directs the tote or case to a “jackpot lane.” Employees working this jackpot lane are dedicated problem solvers that need to identify with which store’s order this case or tote is associated. Determining this may be easy when the bar code exist and is still legible. However, the bar code may be missing entirely or be damaged. Thus, it is quite possible that the store-specific pallets get shipped to stores without specific cases or totes. Fixing the inventory record then requires a manual intervention once DC employees identify the items in the jackpot lane.

Slotting Integrity

Slotting integrity refers to the misplacement of product that can occur during the put-away process. Stock keepers can mistakenly place an entire pallet of SKUs in the wrong location. Because it is often difficult to differentiate between shelves and even aisles

within the warehouse, it is possible for DC employees to mistakenly place a pallet on the wrong shelf.

To help limit this problem, some retailers require a stock keeper to scan the pallet license plate and the shelf location to ensure a match. However, it is still possible to scan the correct bar code of the pallet and the location and still place the product in a neighboring slot. Recognizing this, retailers have tried to make some improvements to signage by adding arrows that show whether the location bar code corresponds to the slot above or below the shelf.

Exacerbating the problem of slotting integrity is the problem of product overflow. When there is not enough capacity in the designated location, overflow products are often stacked down on the floor nearby the assigned area. Movement of the product from the floor into the assigned location is not managed by the automated warehousing management system, leaving it prone to error.

The repercussions of slotting errors include an inability to fill a store order due to the misplacement of product within the DC. While the product exists in the warehouse management system, locating it will require additional research and labor. However, an inability to fill a store order will not necessarily result in IRI. Instead, IRI will occur when the slotting error is not identified and a picker selects product from the designated location without checking the SKU number or description. In this scenario, the inventory of two records within one store will be corrupt if the slotting error occurred in the case-pack location and multiple stores if the slotting error occurred in the break-pack locations.

Picking Integrity

Even when product has been stacked and slotted correctly, pickers may pick from the wrong location. According to warehouse managers, it is not uncommon for warehouse employees to be picking from the correct location in terms of shelf number but to be on the incorrect floor. And, even if they are picking from the right location, and the right floor, it is still possible to pick from the wrong bin. Many retailers arrange its aisles similarly to the aisles of their store (i.e., similar products grouped together) and employees are expected to move rapidly back and forth along the aisle, selecting inventory from a range of locations. Differentiating between similar items is difficult when there is only time to quickly scan the product in a particular slot and compare that item to the one on the pick list. Moreover, slots in the break-pack pick locations may become contaminated with stray products. Break-pack items can fall down shelves or slide to an adjacent shelf and such movement often goes unnoticed by warehouse employees since it is extremely difficult to differentiate similar items contained in generic cardboard cartons.

The selection of the wrong item, has repercussions for the inventory of the store. The wrong product will be sent to the store while the record will be updated to reflect the receipt of the product the DC planned to have picked. Consequently, two inventory records

in one store will inaccurately reflect the quantity of that item.

Quantity Integrity

In addition to picking the right product, pickers are expected to pick the right quantity of that product. Employees can miscount, selecting, for example, 15 units of a given product rather than the requested 13 units. And, employees could also confuse items on the pick list. For instance, a pick list that requests 10 units of item A be selected and placed into a tote along with 5 units of item B could be misread as the employee places 5 units of item A into a tote along with 10 units of item B.

“Unit of measure” problems also occur when an employee confuses the quantity noted on the pick list. For example, a pick list could request one case and the picker mistakenly picks one item. This is particularly true in the break-pack area where manufacturer’s packaging must be opened by the picker at the shelf. Manufacturers may have introduced a new SKU which is a two-pack of, say, batteries. The picker mistakenly breaks these two packs into two separate items. In this instance, when the picker selects one unit from this location, one item is taken rather than the one two-pack. Another example where such mistakes can arise is when the manufacturer packs a case of screws and has packed certain quantities of screws within plastic bags that are then shipped in the case. A picker may be asked to pick one unit from a certain location and it is unclear whether that one item means one individual screw or one plastic bag of screws.

Such picking errors result in store-level IRI. The store receives a tote that fails to contain the correct inventory, while its records, upon receiving the tote, have been updated under the assumption of perfect execution by the picker. Quantity errors, unlike other errors, impact only one SKU per store. However, quantity errors such as the ones described also cause problems for the DC inventory management.

Shipping Integrity

Once an item has been picked, it is sent via conveyor belt to the appropriate shipping lane for the store that has ordered that item. At this point in time, DC employees place the totes and cases onto store-specific pallets that will be loaded onto outbound trucks. The shipping lanes are located very close to each other separated only by lines on the floor. The store-specific pallets that are built by these employees may end up on the wrong truck. While this error is often caught as the truck has fixed capacity such that only a certain number of pallets will fit, fixing the errors does take time. Specifically, products need to be off-loaded from the truck in an effort to find the incorrect pallet. If the warehouse identifies the error prior to the release of the final invoice, the products are removed from the truck and ultimately do not cause a data discrepancy. If the error is not observed in advance, a data discrepancy can occur.

Finally, shipping integrity can be compromised by the truck drivers during the unloading process. If the truck has been loaded incorrectly—meaning the pallets are not placed in the truck in the reverse order of the truck drivers route—the driver has to off load the pallets of other stores in order to locate and unload the pallets for the current delivery. It is then the driver's responsibility to get all the totes for the other stores back onto the truck and proceed to the next store. This may not happen. When it does not, store managers may not assist the driver or the DC in locating the inventory. To the store manager, this additional pallet is "free"—meaning they do not incur the cost of goods sold on their store operating budget but they do reap all the reward—sales dollars.

These shipment errors are significant because they not only cause errors in multiple SKUs at one store but they also cause inaccuracies in the inventory of multiple stores. On the other hand, because they involve large dollar amounts, these types of errors are often more readily caught at the store than some of the other errors previously described. Store managers often receive an itemized list of the products scheduled for

delivery and use this list to verify receiving the appropriate number of pallets from the drivers. Yet, there is no mechanism in place to prevent a driver from unloading a pallet at the wrong store. Moreover, few retailers verify, at the item level, whether what was received matches what was expected for several reasons. First, this is an extremely time-consuming task that requires a lot of labor and delays getting the inventory onto the store floor where customers can make a purchase. Second, even if they were to find a discrepancy, many retail-owned DCs have policies in place that discourage the reporting of such discrepancies. Such policies often do not allow the DC to credit stores for shipment discrepancies on items less than a certain threshold. Thus, store employees only verify the quantity of these expensive items while discrepancies in the inventory record for other items will persist until a routine physical inventory count triggers the updating of the recorded inventory.

DOCUMENT INTEGRITY

Receivers are expected to verify that the quantity per case actually reflects the quantity per case noted in the warehouse information system. When the inventory system has outdated information regarding the quantity per case, the inventory record updated at receiving will be inaccurate. Moreover, the picking will be negatively impacted as well. The system generates one label per case on a pick list. If the store order calls for 24 units and the system thinks there are 24 units per case, one label will be generated, a picker will be directed to pick one case, and the store will receive one case. Suppose that the case did not contain 24 units but actually contained only 12 and this was not corrected during the receiving process. The pick list would still say pick one case, one label would be generated, and once the case departs the DC on a truck bound for a store, the inventory records of the store are updated to reflect this case of 24 units. However, in reality, a discrepancy of 12 units exists due to the lack of document integrity.

This problem is exacerbated by special promotions offered by vendors. For example,

HP might run a special promotion on printer ink where they package two of the same SKU together. When they package these inkjet cartridges, they place a total of 12 of these promotional units in the case but one of these promotional units amounts to two units of the actual item. If this promotion unit does not have its own SKU, it is unclear how best to receive these units. Does the case contain 12 or 24? This complexity continues into different stages when pickers are directed to pick one unit of this SKU—does this unit of measure refer to the one promotional unit or to the one individual unit?

Another type of documentation error is the mislabeling either by vendors or by the receivers. It is possible that the bar code on a case received from the manufacturer does not accurately reflect the content of that case. Receivers are expected to open a few of the cases to verify contents but, given that not all cases are checked, such mislabeling can persist. When a case is mislabeled, it will be mistakenly placed on the wrong pallet, compromising the integrity of that pallet. Receivers may also apply erroneous license plates to pallets. Often, these license plates are printed on long strips and receivers are required to manually match the labels with the correct pallets—a process that can be easily circumvented by receivers. When a pallet is mislabeled, ultimately it compromises the integrity of the location such that the inventory system thinks that the product is located on one shelf when it is actually located elsewhere.

When an incorrect bar code has been placed on a pallet during the receiving process, the pallet could be misplaced. The bar code system ultimately relies on the stock keeper to catch mistakes through visual confirmation. However, since the stock keeper is operating under time pressure to put-away stock, the stock keeper can easily misplace stock and perform an override—not catch an incorrect labeling problem or forget to scan the item into its location entirely.

A reliable replenishment process requires that the right item, in the right quantity, with the right documentation is received, stored, and then shipped to stores. However, table 1 summarizes such errors as an obstacle

to reliability across one item, many items, and throughout the chain. Errors that occur at the beginning of the replenishment process, when undiscovered, persist throughout the rest of the replenishment process. Even if errors are uncovered, fixing them often requires manual intervention, which is also prone to error (e.g., entry errors, omissions errors) to correct the inventory management system.

The Impact of Different Error Types

	One SKU	Multiple SKU	One Store	Multiple Stores
Sorting integrity		X	X	
Slotting integrity		X	X	X
Picking integrity		X	X	
Shipping integrity		X		X
Quantity integrity	X		X	
Document integrity		X		X

FUTURE RESEARCH

There exist many unanswered questions regarding IRI. Two that require additional attention include:

1. Why are retail employees more likely to make mistakes in contexts with high product variety and high inventory density, two known drivers of IRI? Past research has identified these factors as exacerbating the record inaccuracy problem. However, this work falls short in explaining why. Instead, DeHoratius and Raman [3] propose that inventory density and product variety are proxies for confusion in the retail context and that such confusion makes it more likely for retail associates to make a mistake. What might a retailer do to mitigate the impact of product variety and inventory density on IRI? Is it feasible to design product packaging in such a way that ensures fewer mistakes in replenishment and sales transactions? Might retailers benefit from designing shelving in stores and DCs that make

it less likely for mistakes to arise? To address some of these questions, researchers will need to employ behavioral operations methods. Such studies of the behavior of individuals and teams within specific contexts would help identify the precise relationship between retail contexts, ones with high variety and high density, and the occurrence of IRI.

2. Retailers continue to question whether the cost of implementing key process improvement techniques aimed at solving IRI can be offset by the potential gains from reducing IRI. Given the dearth of publicly known pilot projects attempting to address IRI through process improvement mechanisms, this question continues to arise. Researchers need to evaluate the performance of different improvement mechanisms in the field.

In addition to these two key questions, we also feel that existing demand forecasting techniques can benefit from incorporating IRI and that the accuracy of selected forecasts depends on the degree to which the inventory record accurately reflects what is physically present in the store.

Among those who have specifically analyzed the problem of IRI [8,9,18,34–35], none provides an in-depth study of the role of human error and, consequently, imperfect execution as a potential source of IRI. Humans, when engaged in any organizational process, will inevitably make mistakes [36,37]. Reason [38] grouped these mistakes into three different categories: knowledge-based errors, rule-based errors, and skill-based slips and lapses. Knowledge-based errors arise from humans attempting to solve a problem that is unfamiliar to them. Rule-based errors arise when humans apply the wrong rule to a situation or elect not to apply an existing rule. Skill-based slips and lapses are essentially failures in execution. A procedure exists but for some reason the existing procedure is not carried out for some routine activity.

Why such errors occur has been a matter of much discussion among human factors and human reliability scholars. In fact, research into the cause of error in organizational processes has resulted in numerous taxonomies to describe how characteristics of the individual, task, team, and organization, for example, impact human performance. Swain and Guttman [39] provide one often referenced taxonomy where internal performance shaping factors (the individual skills, ability, attitudes, and other characteristics a worker brings to the job), external performance shaping factors (situation characteristics, task, equipment, and procedural characteristics), and psychological and physiological stressors affect a worker's performance of tasks within an organizational system. Kim and Jung [40] provide a comprehensive review of these taxonomies and offer a single taxonomy that synthesizes existing work in this area. According to Kim and Jung [40], human performance depends on individual capabilities and characteristics, the physical characteristics of the organizational process, the procedures and tasks required of the individual, and an environmental influence that includes characteristics of the team and culture of the organization.

The impact of human error has been discussed in numerous contexts including hospitals [41], nuclear plants [39,44], chemical plants, aerospace [45], and orienteering [46]. In these contexts, concern over prevention of catastrophic accidents is of primary concern. The possibility of human error contributing to systemwide failure, the consequence of which has impact for human life, sets research in these contexts apart from our own. Research on human error in the DC context is more similar to research on the impact of human error on delivering service quality to both external [37] and internal customers [47,48]. The impact of service failures, like the impact of IRI, is not as readily visible to the outside as the impact of catastrophic failure in these other contexts. Instead, service failures and the presence of IRI both impose excess cost on the organization, but measuring this cost is difficult due the subtlety of tracking changes in customer behavior.

APPENDIX: FIELDWORK ACTIVITIES AND SITE DESCRIPTION

The core of our observations were drawn from data gathered and interviews conducted at two Gamma⁶ DCs, 15 Gamma stores, and corporate headquarters. Gamma Corporation is a large public retailer with annual sales of roughly \$11 billion and more than 1500 stores worldwide. Since Gamma's founding more than 15 years ago, it has grown to employ over 50,000 people and is currently the largest operator of superstores in the world for its specific product category. Despite its reputation as a leader in its field and the perception that Gamma is an advanced user of information technology, inaccurate inventory records are present in each of the 37 stores observed by DeHoratius and Raman [3].

A typical Gamma store is approximately 24,000 sq. ft in size and is served by one of three DCs which range in size from 310,000 to 830,000 sq. ft. Although Gamma stores receive merchandise from their assigned DC, but they also can receive merchandise directly from vendors. This article focuses only on those items shipped to Gamma stores from the retail-owned DC. Previous work on IRI reveals that items shipped from the retail-owned DCs possess the least accurate records, controlling for differences in product category, stores, the cost of an item, and the quantity it has sold throughout the year [3].

Collectively, we have spent more than 12 weeks in the field observing DC processes across a wide variety of retailers in order to develop inductively our insights on distribution process quality and implications of process defects for the management of retail supply chains. Where possible, we recorded our interviews using a hand-held tape recorder and transcribed these tapes immediately following site visits. Otherwise, we took detailed notes by hand. We also, when permitted, took pictures to document our observations. We did not make any attempt to measure the frequency of error occurrence; but rather our intent was to identify and classify the types of errors that arise.

Our objective in conducting this fieldwork was to understand how inaccurate inventory records arise in Gamma stores. Such qualitative methods are appropriate when the phenomenon of interest is not well understood and detailed observations are required for categorization and theory-building [50].

IRANIAN OPERATIONS RESEARCH SOCIETY (IORS)

NEZAM MAHDAVI-AMIRI
Department of Mathematical
Sciences, Sharif University of
Technology, Tehran, Iran

Iranian Operations Research Society (IORS) was established in 2005 after the approval of its constitution by the Ministry of Science, Research, and Technology in Tehran, Iran. Shortly afterwards, in July 2005, a meeting of interested scholars was held and the first Executive Council of the Society was formed by election. The Society was officially approved to join IFORS as the 50th national member on 16 December 2009. Currently, the society is being managed by its second executive council to be replaced by the third executive council in May 2010 (the term for the council is two years).

IORS currently has 134 members, mostly composed of college scholars and industry professionals. The scholars are mostly from the departments of mathematics, industrial engineering, and management sciences.

The activities of the Society are summarized below:

1. enhancing scientific and cultural research at national and international levels among the researchers and experts who deal with operations research;
2. cooperating with administrative, scientific, and research agencies in evaluating and reviewing plans and programs related to education and research issues concerning the society's interests;
3. promoting researchers and distinguishing successful researchers by honoring them;
4. rendering educational and research activities;
5. publishing books and international journals;

6. organizing scientific gatherings at national, regional, and international levels by holding regular internal seminars and international conferences.

The principal decision-making body of IORS is its general assembly. There is one yearly regular meeting of the assembly as well as additional emergency meetings, when required. The assembly is formed by the permanent members of IORS and is responsible for upholding, modifying, and amending the constitution. It also has the responsibility to vote for the election of the executive council of IORS (with seven main and two reserved members) and the inspectors (one main and one reserved) for orderly execution of the IORS constitution as well as its management of daily affairs. The main members of the elected executive council then decide upon the President, the Vice-President, and the Treasurer of the council at their first meeting. The main members for the first two executive councils and the main inspector are as follows:

IORS's First Executive Council Members and Inspectors:

- Dr. Korosh Eshghi, Department of Industrial Engineering, Sharif University of Technology, Tehran
- Dr. Hasan Salehi Fathabadi, Department of Mathematics and Computer Science, University of Tehran, Tehran
- Dr. Qolamreza Jahanshahloo, Department of Mathematics and Computer Science, Tarbiat Moallem University, Tehran
- Dr. Ahmad Makoui, Department of Industrial Engineering, Iran University of Science and Technology, Tehran
- Dr. Nezam Mahdavi-Amiri (Vice-President), Department of Mathematical Sciences, Sharif University of Technology, Tehran
- Dr. Azizollah Memariani (President), Department of Industrial Engineering, Tarbiat Modarres University, Tehran

Dr. Mohammad Modarres Yazdi (Treasurer), Department of Industrial Engineering, Sharif University of Technology, Tehran

Dr. Mohammad Reza Hamidi Zadeh (Inspector), Department of Management and Accounting, Shahid Beheshti University, Tehran.

IORS's Second Executive Council Members and the Inspector:

Dr. Farhad Hosseinzadeh Lotfi, Department of Mathematics, Azad University Research Center, Tehran

Dr. Qolamreza Jahanshahloo, Department of Mathematics and Computer Science, Tarbiat Moallem University, Tehran

Dr. Nezam Mahdavi-Amiri (Vice-President), Department of Mathematical Sciences, Sharif University of Technology, Tehran

Dr. Azizollah Memariani (President), Department of Industrial Engineering, Tarbiat Modarres University, Tehran

Dr. Mohammad Modarres Yazdi, Department of Industrial Engineering, Sharif University of Technology, Tehran

Dr. Abbas Seifi, Department of Industrial Engineering, Amirkabir University of Technology, Tehran

Dr. Reza Tavakoli Moghadam (Treasurer), Department of Industrial Engineering, University of Tehran, Tehran

Dr. Mohammad Reza Hamidi Zadeh (Inspector), Department of Management and

Accounting, Shahid Beheshti University, Tehran.

IORS publishes the international scientific journal, *Iranian Journal of Operations Research (IJOR)*. The publication is semianual and was first published in 2009.

IORS also organizes the annual International Conference of Iranian Operations Research Society. The first of these conferences was held in 2008. Below is a list of scientific gatherings from the first three years of this conference:

The first International Conference of Iranian Operations Research Society, Jan. 28–30, 2008, Kish University branch of Sharif University of Technology, Kish Island, Iran.

The second International Conference of Iranian Operations Research Society, May 20–22, 2009, Mazandaran University, Babolsar, Iran.

The third International Conference of Iranian Operations Research Society, May 5–6, 2010, Amirkabir University of Technology, Tehran, Iran.

It is important to note that about 600 papers were submitted to the scientific committee of the third conference, and approximately 200 were selected for oral presentations and 100 were selected as posters.

For more information, the reader may visit the website of IORS at: <http://www.iors.ir>.

JACKSON NETWORKS (OPEN AND CLOSED)

HANS DADUNA
Center of Mathematical Statistics
and Stochastic Processes
Department of Mathematics,
University of Hamburg,
Hamburg, Germany

DESCRIPTION OF JACKSON NETWORKS AND FUNDAMENTAL PROPERTIES

We describe classical queueing network theory, which is the fundamental of the rich class of stochastic network models available today. These networks are built on exponential multiserver queues, see the section titled “Single-Station Queues CTMC Models” in this encyclopedia.

Definition 1 [M/M/s/N: Exponential Multiserver Queues]. This is a service station with $s \geq 1$ service channels and a linear waiting room of length N under (first-come first-served (FCFS) regime, $0 \leq N \leq \infty$). Indistinguishable customers arrive in a Poisson- λ process at the station and request for an amount of work (service time) which is exponentially distributed with mean μ^{-1} . All service times are independent and independent of the arrival stream. If an arriving customer finds free service channels, he selects one of them randomly and service commences immediately. If he finds all channels busy and there is free waiting room, he joins the tail of the waiting line; otherwise, this customer is lost. If a service expires, the customer at the head of the line immediately enters the free service channel and the other customers in the waiting line move one step ahead. Let $X(t)$ denote the number of customers in the system at time $t, t \geq 0$. We call $X(t)$ the queue length ($\equiv$ customers waiting or in service). $X = (X_t : t \geq 0)$ is a Markov process with

state space $\mathbb{N}^J$. Unless otherwise specified, our systems will always have infinite waiting room.

Network Models and Steady-State Behavior

Definition 2 [Jackson Network]. A Jackson network is a network of service stations (nodes) numbered $\{1, 2, \dots, J\} := \tilde{J}$. Station j is a multiserver station with $s_j \geq 1$ service channels and an infinite waiting room under the FCFS regime. Customers in the network are indistinguishable. At node j , there is an external Poisson- λ_j arrival stream, $\lambda_j \geq 0$. Customers at node j request for an amount of work (service time) there which is exponentially distributed with mean $\mu_j > 0$. Service times and inter-arrival times are independent.

Movements of the customers follow a Markovian routing mechanism: A customer on leaving node i visits node j next with probability $r(i, j) \geq 0$, entering node j immediately; with probability $r(i, 0) \geq 0$, this customer leaves the network immediately ($\sum_{j=0}^J r(i, j) = 1, \forall i$). Given departure node i , the customer's routing is independent of the network's history. With $\lambda := \sum_{j=1}^J \lambda_j$ and $r(0, j) := \frac{\lambda_j}{\lambda}$ the matrix $R := (r(i, j) : i, j = 0, 1, \dots, J)$ is assumed to be irreducible.

Let $X_j(t)$ denote the number of customers at node j at time $t \geq 0$, either waiting or in service (local queue length at node j); then $X(t) := (X_j(t) : j = 1, \dots, J)$ is the joint queue length vector of the network at time t . $X = (X(t) : t \geq 0)$ is the joint queue length process of the Jackson network.

Theorem 1 [1]. *The joint queue length process X of the Jackson network is an irreducible Markov process with state space $E = \mathbb{N}^J$. The traffic equation of the network*

$$\eta_j = \lambda_j + \sum_{i=1}^J \eta_i r(i, j), \quad j = 1, \dots, J, \quad (1)$$

has a unique solution, denoted by $\eta = (\eta_1, \dots, \eta_J)$, see Proposition 1 for an interpretation.

X is ergodic if and only if $\eta_j < \mu_j s_j, j = 1, \dots, J$, holds. The unique stationary and limiting distribution π on E of X is given as follows. Let π_j denote the local probability for node j ,

$$\pi_j(n_j) = \begin{cases} K_j^{-1} \left(\frac{\eta_j}{\mu_j} \right)^{n_j} \frac{1}{n_j!}, & \text{if } n_j \leq s_j \\ K_j^{-1} \left(\frac{\eta_j}{\mu_j} \right)^{n_j} \frac{1}{s_j!} \left(\frac{1}{s_j} \right)^{(n_j - s_j)}, & \text{if } n_j \geq s_j, \end{cases}$$

where K_j is the normalization constant. Then π is of product form

$$\pi(n_1, \dots, n_J) = \prod_{j=1}^J \pi_j(n_j), \quad (n_1, \dots, n_J) \in E.$$

Product-Form Equilibrium. The local queue lengths $X_j = (X_j(t) : t \geq 0)$ in equilibrium at a fixed time point are independent. But the processes X_j are not independent. They strongly interact via the moving customers. Jackson proved precisely the following: The one-dimensional marginals in time of the vector-valued stationary Jackson network process have independent coordinates in space.

Note, that something more is behind the product form: In equilibrium, the local queue lengths follow in a first-order description the linear interdependence relation (1), while the random fluctuations around the mean values are independent over space for any fixed time instant. On the other side is computing $\text{cov}(X_i(t), X_j(t+s))$ for $s > 0$, an unsolved problem even for $i = j$.

The form of the local equilibria π_j suggests that, in steady-state, node j acts like an isolated $M/M/s_j/\infty$ with Poisson- η_j arrivals. But, in general, the customer flows in the network are not Poissonian [2]. A survey on customer flow processes is given in Disney and König [3], and further details are in Disney and Kiessler [4].

Definition 3 [Gordon–Newell Network]. Consider the set of multiserver nodes

$\tilde{J} = \{1, \dots, J\}$ as described in Definition 2 without external arrivals. There are $I > 0$ customers cycling according to an irreducible Markov matrix $R = (r(i, j) : i, j = 1, \dots, J)$. Service times are as in the open network and the independence of service times and routing decisions hold as well.

Let $X_j(t)$ denote the number of customers at node j at time $t \geq 0$, waiting or in service (local queue length at j). $X(t) := (X_j(t) : j = 1, \dots, J)$ is the joint queue length vector of the network at time t . $X = (X(t) : t \geq 0)$ is the joint queue length process of the Gordon–Newell network.

Theorem 2 [5,6]. The joint Markovian queue length process $X = (X(t), t \geq 0)$ of the Gordon–Newell network is ergodic with state space $S(I, J) = \{(n_1, \dots, n_J) \in \mathbb{N}^J : n_1 + \dots + n_J = I\}$. Let $\eta = (\eta_1, \dots, \eta_J)$ denote the unique probability solution of the traffic equation

$$\eta = \eta R. \quad (2)$$

The unique stationary and limiting distribution $\pi = \pi(I, J)$ of X on $S(I, J)$ is

$$\pi(I, J)(n_1, \dots, n_J) = G(I, J)^{-1} \prod_{j=1}^J \left\{ \prod_{k=1}^{n_j} \frac{\eta_j}{\mu_j(k)} \right\}, \quad (n_1, \dots, n_J) \in S(I, J), \quad (3)$$

where $\mu_j(n) = \min(n, s_j), n \geq 0$ and $G(I, J)$ is the normalization constant.

Product-Form Equilibrium. The steady-state distribution $\pi(I, J)$ of the Gordon–Newell network process is said to be of product form as well. From Equation (3), the Gordon–Newell network equilibrium looks like being obtained from a Jackson network equilibrium by conditioning on the fixed number of customers. Therefore, $\pi(I, J)$ is negatively associated [7].

Visiting Ratios. The solution of the traffic equation (2) is not unique, but only fixed up to a constant factor. Our choice has the natural interpretation of η_j being the visit ratio of customers at node j . The stochastic solution of

Equation (2) is the steady-state distribution of the customers' migration chain. The choice of the factor for η has no influence on the steady-state distribution π in Equation (3).

Corollary 1 [Networks with State-Dependent Service Intensities]. *Consider a Jackson network or a Gordon–Newell network of the structure described in Definitions 2 and 3, but with single server nodes with state-dependent service intensities which are node (j) and locally state (k_j) dependent: Substitute $\mu_j(n) \leftarrow \min(n, s_j)$. Under ergodicity in the open network and in the closed network, in general, we have steady-state product-form results. Jackson Network with State-Dependent Single Servers.*

$$\pi(n_1, \dots, n_J) = \prod_{j=1}^J \left\{ K_j^{-1} \prod_{k=1}^{n_j} \frac{\eta_j}{\mu_j(k)} \right\},$$

$$(n_1, \dots, n_J) \in \mathbb{N}^J.$$

Gordon–Newell Network with State-Dependent Single Servers.

$$\pi(I, J)(n_1, \dots, n_J) = G(I, J)^{-1} \prod_{j=1}^J \left\{ \prod_{k=1}^{n_j} \frac{\eta_j}{\mu_j(k)} \right\}.$$

$$(n_1, \dots, n_J) \in S(I, J).$$

The network processes do not describe individual customer's behavior. To describe individual customer's behavior with more versatile migration, there are two different (equivalent) methods [8]: Random routing as used in the celebrated BCMP networks [9] and deterministic routing as described by Kelly [10, Chapter 3].

Definition 4 [Mixed Networks with Deterministic Routing]. We consider a network of exponential nodes $\tilde{J} = \{1, \dots, J\}$ according to Definition 1, node j having s_j identical service channels, with FCFS regime, providing service which is exponentially distributed with mean μ_j^{-1} . For a simple description, we assume that all positions where customers may be located are linearly ordered: at node j , positions $1, \dots, s_j$ represent the service channels,

position $s_j + 1$ houses the customer at the head of the queue, and so on.

The network serves a finite population of internal customers numbered $1, \dots, M, M \geq 0$. At any time, internal customer m is of some type $t \in T(m)$. Further, external customers arrive at the network, being of some type $t \in T(0)$. The sets $T(m), m = 0, 1, \dots, M$, are countable and pairwise disjoint. With each type $t \in \bigcup_{m=0}^M T(m)$ is associated the finite route $r(t) = [r(t, 1), \dots, r(t, S(t))]$, which a customer of type t follows. Multiple visits to nodes on a route are allowed.

External customers of type $t \in T(0)$ arrive in a Poisson stream with rate $\lambda_t > 0$, enter node $r(t, 1)$, and after leaving that node immediately jump to node $r(t, 2), \dots$, and being finally served at node $r(t, S(t))$, they depart from the network. Inter-arrival times and service times are independent.

Internal customer m , of type t , travels route $r(t)$, thereafter changes to type $t' \in T(m)$, and travels route $r(t')$ with probability $p_m(t, t')$, where $P_m = (p_m(t, t') : t, t' \in T(m))$ is an irreducible positive recurrent stochastic matrix. Given the previous type t , the type decision is independent of the network's history.

Using type-stage sequences, the state description is as follows: For node j , the local state $e_j \in E_j$ indicates node j to be empty and $z_j = [t_{j1}, s_{j1}; t_{j2}, s_{j2}; \dots; t_{jn_j}, s_{jn_j}] \in E_j$ indicates that there are n_j customers present, on position $p \in \{1, \dots, n_j\}$ resides a customer of type t_{jp} being on stage $s_{jp} \in \{1, \dots, S(t_{jp})\}$ of his route $r(t_{jp})$. E_j is the local state space of node j . Global states are compounded of local states, and the global state space E contains all feasible states

$$z = [z_1, \dots, z_J] \in E \subseteq \prod_{j=1}^J E_j.$$

Theorem 3 [Steady-State Distribution for Mixed Exponential Networks]. *For the mixed exponential network of Definition 4, let $Z = (Z(t) : t \geq 0)$ be the Markovian type-stage process (generalized queue lengths process) with state space E . We assume that Z is irreducible on E .*

For internal customers we define the traffic equations $\alpha_m = \alpha_m P_m, m = 1, \dots, M$

and denote their stochastic solution by $\alpha_m = (\alpha_m(t) : t \in T(m))$. Assume furthermore

$$\forall m = 1, \dots, M : \sum_{t \in T(m)} \alpha_m(t) S(t) < \infty \text{ holds,}$$

$$\text{and } \sum_{t \in T(0)} \lambda_t S(t) < \infty.$$

For $j \in \tilde{J}$, $t \in \bigcup_{m=0}^M T(m)$, $1 \leq s \leq S(t)$, denote

$$\eta_j(t, s) = \begin{cases} \lambda_t & \text{if } t \in T(0) \\ \alpha_m(t) & \text{if } t \in T(m), m \in \{1, \dots, M\}. \end{cases}$$

If Z is ergodic, the unique stationary and limiting (product form !) distribution π of Z on E is for $z = [z_1, \dots, z_J] \in E$ with generic local states $z_j = [t_{j1}, s_{j1}; t_{j2}, s_{j2}; \dots; t_{jn_j}, s_{jn_j}]$, $j = 1, \dots, J$,

$$\pi(z_1, \dots, z_J) = K^{-1} \prod_{j=1}^J \left\{ \prod_{k=1}^{n_j} \left(\frac{\eta_j(t_{jk}, s_{jk})}{\mu_j(k)} \right) \right\}, \quad (4)$$

where $\mu_j(n) = \mu_j \cdot \min(n, s_j)$ and $K < \infty$ is the normalization constant.

Observing Networks at Embedded Time Points-Customer Stationary Distributions

The results on steady-state distributions of the product form presented in the section titled “Network Models and Steady-state Behavior” were extended to more complex networks especially in Baskett *et al.* [9] and Kelly [10]. From these probabilities, the main first-order performance indices of the networks can be obtained, for example, throughputs, mean queue lengths, and via Little’s theorem, mean passage times, see the section titled “Performance Measures and Algorithms” for algorithms and the article titled **Little’s Law and Related Results** in this encyclopedia for details. But it became apparent soon that, for obtaining passage time quantiles, somewhat different distributions were needed. Describing individual customer’s behavior on a route commences with observing “arrival distributions,” which describe the *network’s disposition* from the view of a customer who

enters a station—usually the disposition distributions are not in Equation (4). For open networks, early results of Strauch [11] and Wolff [12,13] were already available. These results stated that “Poisson arrivals see time averages (PASTA),” the celebrated PASTA property; or, as Strauch [11] puts it: When a queue looks the same to an arriving customer as to an observer, differentiating the “time stationary” and the “customer stationary distribution”.

For closed multi-type networks, the problem of determining arrival distributions was solved concurrently by Lavenberg and Reiser [14] and Sevcik and Mittrani [15].

There has been a rapid development of much more general results since then; an early example is given in Melamed [16], where for a general Markovian jump process $(X_t : t \geq 0)$ and an embedded sequence $(T_n : n \in \mathbb{N})$ of stopping times the distribution of X_{T_n+} and of X_{T_n-} are obtained. Melamed applied the results to open Jackson networks of queues, and to their generalization from Baskett *et al.* [9] and Kelly [10]. This approach could be used to prove results like Theorem 4 below.

Several extensions of the framework are obtained by Melamed himself, Whitt [17,18], Wolff [19], König [20], and Schmidt [21], who termed a generalized relation between time-stationary distributions of a process and the distribution at embedded time sequences “Embedded points see time averages” (EPSTA). Deviation of the Poisson property was also investigated under the heading of “Arrivals see time averages” (ASTA) in Melamed and Whitt [18]; Wolff [19] and Green and Melamed [22] proved for suitable systems an ANTI-PASTA property, which states conditions under which ASTA implies that the embedded sequence is Poisson. A similar result for EPSTA can be found in Green and Melamed [21].

On describing the network processes in terms of marked point processes, it is seen that the described results can be interpreted as results on Palm probabilities for the processes, for a survey see Serfozo [23] (Chapter 4). For more details on PASTA and related results, see the article titled **PASTA and Related Results** in this encyclopedia.

Sojourn Time and Passage Time Distributions for Individual Customers

Describing individual customer's behavior on a route commences with observing "arrival distributions," which determines the time-stationary behavior. These arrival distributions are distributions for the dispositions of the network at embedded time points, which in the present framework is often called *customer stationary distributions*. We describe the approach via limiting distributions similar to Sevcik and Mitrani [15]. For the approach via point processes, see Kook and Serfozo [24] and Bremaud *et al.* [25], and in more detail in Daduna and Szekli [26].

Denote by $A(t, s) = (A_n(t, s) : n \in \mathbb{N})$ the sequence of time instances when internal customer m being type t enters stage s of his route $r(t)$. Use a similar notation for the sequence of specific jump instances for external customers of type t . If the network's state just after such time instant $A_n(t, s)$ is $z \in E$, then we know that z shows at node $r(t, s) = j$ on position $n_{r(t, s)} = n_j$ the state description $(t_{jn_j}, s_{jn_j}) = (t, s)$. The disposition $d(z)$ of the other customers with respect to the (t, s) jump is obtained from z by deleting the pair $(t_{jn_j}, s_{jn_j}) = (t, s)$. Note that, if t is an external type, the disposition is a state in E , while if t is an internal type, $d(z) \notin E$. If t is an internal type, we denote the feasible set of dispositions by $E_{-t, s}$, which is a subset of the state space of the network when customer m with $t \in T(m)$ is deleted.

Theorem 4 [Arrival Theorem]. *Suppose the network process $Z = (Z(t) : t \geq 0)$ of the mixed network is ergodic. Let $t \in T(0)$ and $s \in \{1, \dots, S(t)\}$. Then the embedded process $Z^{t, s} = (d(Z(A_n(t, s))) : n \in \mathbb{N})$ is an ergodic Markov chain with unique limiting distribution*

$$\pi^{t, s}(z) := \lim_{n \rightarrow \infty} P(d(Z(A_n(t, s))) = z) = \pi(z), \\ z \in E.$$

Let $t \in T(m)$, $m \in \{1, \dots, M\}$, and $s \in \{1, \dots, S(t)\}$. Then the embedded process $Z^{t, s} = (d(Z(A_n(t, s))) : n \in \mathbb{N})$ is an ergodic

Markov chain with unique limiting distribution

$$\pi^{t, s}(z) := \lim_{n \rightarrow \infty} P(d(Z(A_n(t, s))) = z) \\ = \pi(z') \eta_{r(t, s)}(t, s)^{-1} \\ \times \mu_{r(t, s)}(n_{r(t, s)}(z) + 1) C^{-1}, \quad z \in E_{-t, s}, \quad (5)$$

where $n_{r(t, s)}(z)$ is the queue length of the disposition state at node $r(t, s)$ under z , and $z' \in E$ is obtained from $z \in E_{-t, s}$ by inserting the pair (t, s) at node $r(t, s)$ on position $n_{r(t, s)}(z) + 1$ in state z . C is the new normalization constant.

Limiting Versus Stationary Behavior. From Markov chain properties, it follows that the limiting distributions in Theorem 4 are equilibrium distributions of the embedded Markov chains as well. For more details, generalizations, and references, see the short overview in the section titled "Observing Networks at Embedded Time Points - Customer Stationary Distributions."

For open networks, the result is often loosely stated as follows: In equilibrium, an external arrival observes the other customers in the network in steady-state.

For closed networks, the result is often stated as follows: In equilibrium, a customer in a jump instant observes the other customers distributed according to the steady-state of that network, obtained by deleting himself from the population. This is not always correct [27, p. 144/145]. A consequence of this is the cumbersome notation of the limiting distribution (5).

Departure Theorems. We can write a similar framework for what customers observe at departure instants departing from the network or when jumping inside the network. These are covered by EPSTA and similar properties described in the section titled "Observing Networks at Embedded Time Points - Customer Stationary Distributions."

PASTA. While in the open network case customers entering the network from the exterior experience the consequences of the PASTA property and do the same when departing from the system, the jumps inside

the open network need not be Poissonian. Nevertheless, the dispositions seen by the jumping customer look like a PASTA property: This is visible from the formulae in Equation (5). Note that in nontrivial closed networks there are no Poissonian streams.

An immediate consequence of the Arrival Theorem and the strong Markov property of Z is

Theorem 5 [Asymptotic Sojourn Time Distribution]. *For the n th customer of type t traversing route $r(t)$, denote by $(T_1^{(n)}, \dots, T_{S(t)}^{(n)})$ the vector of his successive sojourn times at the nodes of $r(t)$. Then independently of the initial distribution of the system (with $\Theta_s \geq 0, s = 1, \dots, S(t)$),*

$$\lim_{n \rightarrow \infty} E[\exp(-\Theta_1 T_1^{(n)} - \dots - \Theta_{S(t)} T_{S(t)}^{(n)})] \\ = E_{\pi^{t,1}}[\exp(-\Theta_1 T_1^{(1)} - \dots - \Theta_{S(t)} T_{S(t)}^{(1)})]. \quad (6)$$

$E_{\pi^{t,1}}[\cdot]$ is expectation under $P_{\pi^{t,1}}[\cdot]$, the measure which describes the system conditionally on the first $(t, 1)$ jump at time 0 seeing the other customers' disposition distributed according to $\pi^{t,1}$.

In general, routes need more structure for Equation (6) leading to explicit results. Early results of Reich and Burke for linear systems were proved without explicitly introducing customer types.

Theorem 6. (a) [28,29] *In a linear (tandem) Jackson network of single server nodes, that is, $\lambda_1 > 0, \lambda_2 = \dots = \lambda_J = 0$, and $r(J, 0) = r(i, i+1) = 1, i = 1, \dots, J-1$ with $\lambda_1 < \mu_j, j = 1, \dots, J$, in steady-state the sojourn times of a customer traversing the tandem are independent and*

$$\lim_{n \rightarrow \infty} E[\exp(-\Theta_1 T_1^{(n)} - \dots - \Theta_J T_J^{(n)})] \\ = \prod_{j=1}^J \frac{\mu_j - \lambda_1}{\mu_j - \lambda_1 + \Theta_j}, \quad \Theta_j \geq 0, j = 1, \dots, J.$$

Moreover, with nodes 1 and J being multi-server stations, the independence still holds.

(b) [30] *In a cyclic Gordon–Newell network of single server nodes, that is,*

$r(J, 1) = r(i, i+1) = 1, i = 1, \dots, J-1$, *in steady-state the sojourn times of a customer traversing the cycle equal the limiting joint sojourn time vector, given by* ($\Theta_j \geq 0, j = 1, \dots, J$)

$$\lim_{n \rightarrow \infty} E[\exp(-\Theta_1 T_1^{(n)} - \dots - \Theta_J T_J^{(n)})] \\ = \sum_{(n_1, \dots, n_J) \in S(I-1, J)} \pi(I-1, J)(n_1, \dots, n_J) \\ \times \prod_{j=1}^J \left(\frac{\mu_j}{\mu_j + \Theta_j} \right)^{n_j+1}.$$

If the cycle commences at node 1, then with multiservers at nodes 1, J a similar result holds.

These results were extended to sojourn time computations on so-called *overtake-free* paths in open Jackson networks [8,31] and in closed Gordon–Newell networks [32]. A unification and generalization of these results needed the machinery of the notation invented for formulation of the Arrival Theorem. The main concept invented in Schassberger and Daduna [33] is that of a “quasi overtake-free” path (route). For a survey on this and related topics, see Boxma and Daduna [34] and Daduna [35].

Definition 5 [Quasi Overtake-Free Paths]. Consider a mixed network from Definition 4.

1. For nodes $i, j \in \{1, \dots, J\}$, write $i - (t) \rightarrow j$, if $i = r(t, s), j = r(t, s+1)$ for some $t \in \bigcup_{m=0}^M T(m)$, and $1 \leq s < S(t)$, or if $i = r(t, S(t)), j = r(t', 1)$ for some $m \in \{1, \dots, M\}$ with $t, t' \in T(m)$ and $p_m(t, t') > 0$.
2. For type t a t -relevant path $[j_1, \dots, j_K]$ from node j_1 to node j_K is a sequence of nodes (in general not a path or part of a single route) such that $j_k - (t_k) \rightarrow j_{k+1}, 1 \leq k < K$, holds with

$$t_k \in \bigcup_{m=0}^M T(m) \text{ if } t \in T(0)$$

and

$$t_k \in \bigcup_{m=0, m \neq \bar{m}}^M T(m) \text{ if } t \in T(\bar{m}),$$

$$1 \leq \bar{m} \leq M.$$

3. For $t \in \bigcup_{m=0}^M T(m)$, let $[r(t, u), \dots, r(t, v)]$ be a section of different successive nodes of route $r(t)$, $1 \leq u \leq v \leq S(t)$. This section is overtake-free for type t if every t -relevant path from $r(t, u')$ to $r(t, v')$ includes node $r(t, u' + 1)$, $u \leq u' < v' \leq v$.
4. For a customer of type $t \in \bigcup_{m=0}^M T(m)$, his route $r(t)$ is quasi overtake-free if the following holds: There exist u, v with $1 \leq u \leq v \leq S(t)$ such that the section $[r(t, u), \dots, r(t, v)]$ is overtake-free and

$$s_{r(t,1)} = \dots = s_{r(t,u-1)} = \infty,$$

$$s_{r(t,u+1)} = \dots = s_{r(t,v-1)} = 1,$$

$$s_{r(t,v+1)} = \dots = s_{r(t,S(t))} = \infty.$$

Theorem 7 [Sojourn Time Distribution on Quasi Overtake-Free Paths]. For customer of type t , let his route $r(t)$ be quasi overtake-free. For the n th customer of type t traversing route $r(t)$, let $(T_1^{(n)}, \dots, T_{S(t)}^{(n)})$ be the vector of his successive sojourn times at the nodes of $r(t)$. Then, independent of the initial distribution,

$$\lim_{n \rightarrow \infty} E[\exp(-\Theta_1 T_1^{(n)} - \dots - \Theta_{S(t)} T_{S(t)}^{(n)})]$$

$$\Theta_s \geq 0, s = 1, \dots, S(t),$$

$$= \left(\prod_{s=1}^{S(t)} \frac{\mu_{r(t,s)}}{\mu_{r(t,s)} + \Theta_s} \right)$$

$$\times \sum_{(n_{r(t,1)}, \dots, n_{r(t,S(t))})} \pi^{t,s}(n_{r(t,1)}, \dots, n_{r(t,S(t))})$$

$$\times \prod_{p=u}^v \left(\frac{\mu_{r(t,p)} s_{r(t,p)}}{\mu_{r(t,p)} s_{r(t,p)} + \Theta_p} \right)^{(n_{r(t,p)} + 1 - s_{r(t,p)})_+}, \quad (7)$$

where $(a)_+ = \max(a, 0)$, and $\pi^{t,1}(n_{r(t,1)}, \dots, n_{r(t,S(t))})$ is the probability under $P_{\pi^{t,1}}[\cdot]$, to see at time 0 the arriving type t customer at the

tail of the queue at node $r(t, 1)$, and having queue lengths vector $(n_{r(t,1)}, \dots, n_{r(t,S(t))})$ for the number of other customers present at the nodes of $r(t)$.

The steady-state distribution under $P_{\pi^{t,1}}[\cdot]$ of $(T_1^{(n)}, \dots, T_{S(t)}^{(n)})$ is given by Equation (7) as well.

Quasi overtake-free paths occur, for example, in flow shop systems and transmission lines. Note that any two-station route of successive distinct exponential multiserver queues is quasi overtake-free. Slight (part) generalizations of Theorem 7 are in Kook and Serfozo [24] and Daduna [36].

The problem of computing more passage times on more general routes seems to be challenging as is highlighted by the examples: The Simon–Foley network [37] and Burke’s tandem [38].

PERFORMANCE MEASURES AND ALGORITHMS

The success of Jackson networks in applications is due to having access to steady-state distributions and the fact that the main performance indices of the networks can be directly derived from these. We assume therefore throughout this section that all systems are in steady-state. Although explicit formulas are at hand, computational difficulties occurred when evaluating the explicit formulas. A short survey of the extensive bibliography on algorithmic and computational aspects of queueing network performance analysis is in Kant [39]; more details can be found in Bolch *et al.* [40] and Bruell and Balbo [41].

The most important system-oriented performance index is throughput, while the most important customer-oriented index is sojourn time (travel time) of customers.

Proposition 1. For the open Jackson network, the total arrival rate is $\lambda = \sum_{j=1}^J \lambda_j$. From stationarity, it follows that the overall throughput TH , that is, the mean number of departures from the system per time unit, equals the mean number of arrivals at the system per time unit, so $TH = \lambda$.

The mean number of departures per time unit from node j (node- j throughput) is $TH_j = \eta_j$.

For the Gordon–Newell network, arrival and departure rates at any node are identical in equilibrium. The mean number of departures per time unit from node j (node- j throughput) in the network with $I \geq 1$ customers is

$$\begin{aligned} TH_j(I) &= \sum_{(n_1, \dots, n_J) \in S(I, J)} \pi(n_1, \dots, n_J) \cdot \mu_j(n_j) \\ &= \eta_j \cdot \frac{G(I-1, J)}{G(I, J)}, \end{aligned} \quad (8)$$

where η_j is the customers visit ratio at node j , that is, the probability solution of the traffic equation (2). The (overall) throughput of the network is the sum of the local throughputs

$$TH(I) = \sum_{j=1}^J TH_j(I) = \frac{G(I-1, J)}{G(I, J)}. \quad (9)$$

From Proposition 1, the need for computing normalization constants efficiently is obvious. We demonstrate typical techniques for closed Gordon–Newell networks with single servers with state-independent service rates $\mu_j, j = 1, \dots, J$. From Theorem 2, we have with normalization constant $G(I, J)$

$$\begin{aligned} \pi(I, J)(n_1, \dots, n_J) &= G(I, J)^{-1} \prod_{j=1}^J \left(\frac{\eta_j}{\mu_j} \right)^{n_j}, \\ (n_1, \dots, n_J) &\in S(I, J). \end{aligned} \quad (10)$$

The numerical problems with Equation (10) arise from the complexity of $G(I, J)$. Similar sums occur when computing Gibbs measures in statistical physics, where normalization constants are called *partition functions*. In statistical mechanics, from the partition function many observables of the systems can be computed. A similar program has been developed in network theory.

Theorem 8 [Buzen’s Algorithm [42]]. For a closed Gordon–Newell network with J single server nodes and state-independent service rates $\mu_j, j = 1, \dots, J$

we denote for different population sizes by $1 =: G(0, J), G(1, J), \dots, G(I, J), \dots$ the normalization constants of the respective steady-state distributions $\pi(I, J)$. These normalization constants are computed iteratively as follows. Denote

$$x_j = \frac{\eta_j}{\mu_j}, \quad j = 1, \dots, J,$$

$$\text{and } G(i, j) = \sum_{\substack{(n_1, \dots, n_J) \in \mathbb{N}^J \\ n_1 + n_2 + \dots + n_J = i}} \prod_{k=1}^j x_k^{n_k}$$

$$\text{Then } G(i, 1) = x_1^i, \quad i \geq 0,$$

$$G(0, j) = 1, \quad j \geq 0,$$

$$\text{and } G(i, j) = G(i, j-1) + x_j \cdot G(i-1, j), \\ j \geq 2, i \geq 1.$$

Given $x_j = \frac{\eta_j}{\mu_j}, I, J$, to compute $G(1, J), \dots, G(I, J)$, we need $I \cdot J$ additions and $I \cdot J$ multiplications.

Corollary 2. For a Gordon–Newell network from Theorem 8 with I customers denote by $X = (X_1, \dots, X_J)$ a vector distributed like $\pi(I, J)$, that is, X behaves as the network’s steady state. Then

$$\begin{aligned} P(X_j \geq m_j) &= \left(\frac{\eta_j}{\mu_j} \right)^{m_j} \cdot \frac{G(I-m_j, J)}{G(I, J)}, \\ 0 \leq m_j \leq I, \quad j &= 1, \dots, J, \end{aligned} \quad (11)$$

$$\begin{aligned} P(X_j = m_j) &= \left(\frac{\eta_j}{\mu_j} \right)^{m_j} \cdot \left\{ \frac{G(I-m_j, J)}{G(I, J)} - \frac{\eta_j}{\mu_j} \right. \\ &\quad \times \left. \frac{G(I-m_j-1, J)}{G(I, J)} \right\}, \\ 0 \leq m_j \leq I, \quad j &= 1, \dots, J, \end{aligned}$$

$$E[X_j] = \sum_{m_j=1}^I \left(\frac{\eta_j}{\mu_j} \right)^{m_j} \cdot \frac{G(I-m_j, J)}{G(I, J)}.$$

Theorem 9 [Mean Value Analysis, [43]]. We investigate the Gordon–Newell network with J single server nodes and state-independent service rates μ_j with different population sizes I . Fix $\eta = (\eta_1, \dots, \eta_J)$, the unique probability solution of the traffic equation (2). We denote

- $X(I) = (X_1(I), \dots, X_J(I))$, a vector which has distribution $\pi(I, J)$ from Equation (3). $E[X_j(I)]$ is the respective mean local queue length at node j with population size I .
- $T_j(I)$ a random variable which is distributed according to the stationary distribution of the sojourn time of a customer at node $j, j = 1, \dots, J$. $E[T_j(I)]$ is the respective mean sojourn time at node j .
- $TH(I)$ is the stationary throughput of the network. The MVA is

$$E[X_j(0)] = 0, \quad j = 1, \dots, J,$$

and for $I \geq 1$

$$E[T_j(I)] = \mu_j^{-1} (1 + E[X_j(I-1)]), \quad j = 1, \dots, J,$$

$$TH(I) = \frac{I}{\sum_{j=1, \dots, J} \eta_j E[T_j(I)]} \quad (12)$$

$$E[X_j(I)] = \eta_j TH(I) \cdot E[T_j(I)], \quad j = 1, \dots, J. \quad (13)$$

Equation (13) can be written as $E[X_j(I)] = TH_j(I) \cdot E[T_j(I)], j = 1, \dots, J$. This is Little's equation for each node in the network, for details see El-Taha and Stidham [44]. A similar interpretation can be given to Equation (12) by defining the overall mean sojourn time in a queue of the network to be

$$E[T(I)] := \sum_{j=1, \dots, J} \eta_j E[T_j(I)],$$

which yields $I = TH(I) \cdot E[T(I)]$.

MVA yields recursively the main performance measures without probabilities and normalization constants. These can be obtained via normalization constants from Equation (9) and $G(I, J) = \prod_{k=1}^I TH(K)^{-1}$. From Corollary 2, the probabilities are obtained.

EXTENSION OF THE MODELS: ADDITIONAL FEATURES

Model 1 [State-Dependent Arrivals [6]].

If in the Jackson network of Definition

2 there is a total population of size $k = n_1 + \dots + n_J$ present, the arrival intensity is $\lambda(k) \geq 0$. An arrival enters node j with probability $r(0, j)$. All other properties of the network remain the same. If the joint queue length process is ergodic, then its steady-state distribution is

$$\pi(n_1, \dots, n_J) = G^{-1} \prod_{k=1}^{n_1 + \dots + n_J - 1} \lambda(k) \prod_{j=1}^J \left(\prod_{k=1}^{n_j} \frac{\eta_j}{\mu_j(k)} \right) \quad (n_1, \dots, n_J) \in E, \quad (14)$$

where $\mu_j(k) = \mu_j \min(k, s_j)$ in the case of node being a multiserver with s_j channels, η_j is the solution of the traffic equation (1) with λ_j substituted by $r(0, j)$, and G is the normalization constant.

The result (14) holds as well when μ_j are of general form.

If for some $K_0 : \lambda(k) = 0 \forall k \geq K_0$, Equation (14) remains valid for the finite set of feasible states.

For Jackson networks with different customer types where the arrival intensities depend on the number of types already present, a similar result can be proven [10, Section 3.5].

Model 2 [General Service Disciplines, Nonexponential Service Times [9,10]]. Driven by needs in computer science applications around 1975, several classes of generalizations of Jackson and Gordon–Newell networks were developed which still exhibit product-form steady-state. The additional features embedded into the networks were customer classes and types, type-dependent routing, general service disciplines [10], which encompass especially processor sharing, last-come first-served preemptive resume, infinite servers [9] (which are special cases of so-called *symmetric servers*), and type-dependent and nonexponential service time requests at symmetric servers.

Model 3 [Finite Waiting Rooms [6,45]].

If in the Jackson network of

Definition 2 at some nodes have finite waiting room, it must be specified how blocking of customers due to full waiting space is resolved. Jackson proved that the following rules yield a product-form steady-state again (even for state-dependent arrivals as in Model 1): Whenever a customer on his itinerary encounters a station where all service and waiting places are occupied, he jumps over this station in the direction specified by the routing matrix as if he has been served there (“jump-over protocol,” skipping). If the next destination node is full, the protocol applies again—until he will find a node with waiting or service places available or until he will leave the network.

The same protocol was investigated by Pittel [45] in closed networks, obtaining the product-form steady state again. The jump-over protocol has been rediscovered several times in the literature. If in a Gordon–Newell network routing is reversible, another protocol to handle blocking is available which maintains product-form steady-state: A customer on leaving node i finding his destination node full stays on at node i to obtain another service there (“transmission blocking” $\equiv$ transmission is thought to be not successful), for details, see van Dijk [46] and the references there.

Model 4 [Nonergodic Jackson Networks [47]]. If in the Jackson network of Definition 2 there exist η_j from the solution of the traffic equation (1) with $\eta_j \geq \mu_j$, then the network’s joint queue length process is not ergodic, and no steady-state exists. Goodman and Massey proved for networks of single server stations that in this case the generalized traffic equation

$$\eta_j = \lambda_j + \sum_{i=1}^J \min(\eta_i, \mu_i) r(i, j), \quad j = 1, \dots, J,$$

has a unique solution such that $\eta_j < \mu_j, j \in U \subseteq \{1, \dots, J\}$, $\eta_j \geq \mu_j, j \in U^c \subseteq \{1, \dots, J\}$ that is, nodes in U are “stable” whereas nodes in U^c are not. Then, independent of

the initial distribution

$$\begin{aligned} \pi_U(n_i, i \in U) &:= \lim_{t \rightarrow \infty} P(X_i(t) = n_i; i \in U) \\ &= \prod_{i \in U} \left(1 - \frac{\eta_i}{\mu_i}\right) \left(\frac{\eta_i}{\mu_i}\right)^{n_i}, \\ &\quad (n_i, i \in U) \in \mathbb{N}^{|U|} \end{aligned}$$

$$\begin{aligned} \pi_{U^c}(n_j, j \notin U) &:= \lim_{t \rightarrow \infty} P(X_j(t) = n_j; j \notin U) = 0, \\ &\quad (n_j, j \notin U) \in \mathbb{N}^{|U^c|}. \end{aligned}$$

Model 5 [Networks with Unreliable Servers]. Servers in the Jackson or Gordon–Newell network can be unreliable, that is, they break down randomly and are repaired (usually a random time). This is a problem from the intersection of performance analysis and reliability.

Such problems have found much interest in the literature, but results similar to those of Jackson *et al.* are rare. A folk approach to obtain explicit distributional results is the “reduced workload approximation,” which decouples the performance from the reliability part. For any node i , the portion $\alpha_i \in (0, 1]$ of time the node is functioning (available) is determined often approximately without considering details of the load-dependent service mechanism. Thereafter, the node’s service rate μ_i , say, is reduced to $\alpha_i \cdot \mu_i$. With this reduced service rate for all stations, the network is investigated with all other characteristics unchanged, see for related approximations [48].

The problem with this procedure is that it is not possible to model jointly the availability and performance behavior of the network. Systems with product-form steady state to jointly investigate these quantities in an integrated model are developed in Sauer and Daduna [49]. The overall breakdown-repair processes are modeled as multidimensional birth-death processes, the rates of which may depend on the queue length vector. Because nodes that are down do not accept new customers, regulations for redirecting customers which want to enter a broken-down station are set in force: “jump-over protocol” (skipping) and, in case of reversible routing, “transmission blocking,” see Model 3.

Model 6 [Bottleneck Analysis]. It was already observed by Gordon and Newell that in a closed network under heavy load (large number of customers) bottlenecks occur whenever there are different utilizations η_i/μ_i (we sketch only the single server case of Theorem 2). This means that almost all customers queue up at the nodes with highest utilization. There is an enormous bulk of literature on how to deal with asymptotic analysis of a closed network with fixed number J of nodes and routing behavior when the population size $I \rightarrow \infty$ [50].

More detailed studies are in Malyshev and Yakovlev [51] and Daduna *et al.* [52] where, for example, asymptotic throughput under $J \rightarrow \infty$ and $I \rightarrow \infty$ is investigated, concentrating on the existence of critical customer densities determined by the bottlenecks and queue length behavior without rescaling of time and queue lengths.

An observation of Gordon and Newell [5]: If exactly one bottleneck exists, under $I \rightarrow \infty$ the joint queue length vector of the non-bottleneck nodes converges in distribution to the distribution of the joint queue length vector of an open Jackson network, which is fed by a single Poisson stream originating from the bottleneck.

Model 7 [Infinite Routing Graphs]. The extension of the product-form theory of Jackson and Gordon–Newell networks to routing on infinite graphs needs new techniques from functional analysis of Markov processes as it is needed, for example, for Markov interacting processes which describe particle systems on infinite lattice graphs [53]. Some early contributions from the queueing network point of view are described in Karpelevich *et al.* [54] and the references therein.

Model 8 [Discrete Time Networks]. Building product-form networks in discrete-time has a long history [55], but the construction of suitable models was less successful than in continuous-time. The direct approach by substituting “Poisson arrival streams $\rightarrow$ Bernoulli arrival streams,” “exponential service times $\rightarrow$ geometric service times,” maintaining the routing procedures and the usual independence

assumptions, for single server nodes was successful only for linear networks (closed cycles and open tandems).

A network with general routing was constructed by Walrand [56] with a new class of servers (S-queues with batch service and batch arrivals). A variety of applications can be found in Woodward [57]. For more models and further development of the theory, see Refs 58, 59 and 60.

JOB SHOP SCHEDULING

MARC E. POSNER
Integrated Systems Engineering,
Ohio State University,
Columbus, Ohio

In a sequential scheduling problem, jobs must complete a set of tasks or operations. Typically, each task is completed using a specific type of machine or workstation. In the job shop scheduling problem, each job has its own specific set and sequence of tasks that are required for completion. The job shop scheduling problem is one of the three classic sequential multimachine scheduling problems. The requirement regarding the order in which tasks are completed is the distinction between the job shop problem and the other two classic sequential problems, the flow shop and the open shop. In the open shop environment, the tasks for a given job can be completed in any order, and in the flow shop environment, all jobs complete their tasks in the same order.

While numerous variations exist, for the classic job shop problem, the jobs are processed subject to the following conditions:

1. A machine can process only one job at a time.
2. The sequence of machines that a job visits is specified.
3. A job cannot visit a machine more than once.
4. The processing of a job on a machine cannot be interrupted.
5. The input buffer is infinite for each machine.
6. The processing time of a job on a given machine is known.
7. The objective is to minimize the time that is required to complete the last job (the makespan).

The decision for this problem is to specify the order in which the jobs are processed on

each machine. Suppose that there is an idle machine and the next job to be processed by that machine is available. There is no benefit to delaying the processing of that job if the objective is to minimize the makespan, Condition 7. As a result, once the job processing order is decided for each machine, each job is processed as soon as possible, subject to the task order requirements and machine scheduling decisions. Thus, the processing order for each machine determines the exact starting time and completion time of each task.

Many real-world production and service environments can be modeled as job shop scheduling problems. The most typical environments are production shops, where different types of jobs require different treatments. One example is semiconductor wafer manufacturing [1]. Also, repair facilities are usually job shops because different breakdowns require different tools and operations. In the service sector, a common example is the execution of consulting engagements in a management consulting firm.

The job shop scheduling problem is one of the hardest problems in operations research. Almost all versions of this problem are intractable [2]. A 10-machine, 10-job problem was posed by Muth and Thompson [3]. The optimal solution was not verified until Carlier and Pinson [4] solved the problem using a variety of sophisticated mathematical programming techniques and nearly five hours of computer time. While a wide variety of optimization approaches have been considered, none are able to find optimal solutions to large problems. Two such methods are Branch and Bound [5] and Lagrangian Relaxation [6].

Not only is it hard to find optimal solutions, but it is also difficult to generate good quality approximate solutions. The result is that an important area of research has arisen which is based on a procedure that, in the worst case, takes an exponential amount of time (based on the input size) to solve a job shop scheduling problem. This proce-

ture, called the *shifting bottleneck heuristic*, was originally developed by Adams *et al.* [7]. This research area is one of the few in the operations research literature that studies an exponential-time heuristic.

A wide variety of variations on the classic job shop problem have been considered. These variations allow for changes in the objective function, in the constraints and job restrictions, or in the processing approaches. One example is minimizing the work-in-process (WIP) time [5]. By adding due dates to the jobs (suggested completion times), several different objectives have been considered. These include minimizing the sum of lateness [8], minimizing the average cost of early completion (because jobs are held in inventory), late completion, or number of late jobs [9], minimizing the weighted tardiness (Vepsäläinen and Morton), and the maximum tardiness (maximum {job lateness, 0}) [6].

Also, a variety of constraints and restrictions have been considered. These include job deadlines [11], jobs interruption, and later resumption on a machine (preemption) [12], all jobs with unit processing times [13] or with stochastic processing times [14], controlled processing times [15], sequence-dependent setup times [16], machine availability times [17], limited machine buffers [18], insertion of late arriving jobs into the schedule [19], and addition of new tasks for specific jobs [20]. Dauzère-Pérés and Lasserre [21] consider a job shop problem where jobs can be split (lot streaming) to reduce the makespan.

One variation in processing is that a task can be scheduled from a set of flexible machines, which allows for a job to follow multiple routes through the shop [22]. Another variation is considered by Mason

et al. [23] where a job can return to a machine that it previously visited (reentrant job shop).

FORMULATION

To formulate the job shop problem, we first specify the set of problem inputs (parameters). In the classical version of this problem, there are m machines, $M_1, M_2, \dots, M_m$, and n jobs, $1, 2, \dots, n$. Each job $j \in N = \{1, 2, \dots, n\}$ has a set of m tasks, $T_{1j}, T_{2j}, \dots, T_{mj}$, where $T_{ij} = k$ specifies that the k th task for job j is on machine M_i . This vector, $(T_{1j}, T_{2j}, \dots, T_{mj})$, describes the machine processing order for job j . Also, the processing time for job j on machine M_i is denoted by $p_{ij} \geq 0$. The situation where job j is not processed on machine M_i can be modeled by setting $p_{ij} = 0$ and making M_i the first (or last) machine that job j visits. The most common objective is to minimize the makespan.

The problem can be formulated as a mathematical programming problem. The parameters are the machine order and the processing time for each job on each machine. Let

$$y_{ij} =$$

completion time of job j on machine M_i

$$x_{ijk} =$$

$$\begin{cases} 1, \text{ job } j \text{ is processed before job } k \\ \quad \text{on machine } M_i \\ 0, \text{ job } k \text{ is processed before job } j \\ \quad \text{on machine } M_i. \end{cases}$$

One standard mixed integer formulation is

$$\begin{aligned} & \text{minimize } C_{\max} \\ & \text{sub. to } y_{ij} \leq C_{\max}, & T_{ij} = m; i \in \{1, 2, \dots, m\}; j \in N, & (1) \\ & y_{ij} + p_{lj} \leq y_{lj}, & T_{ij} < T_{lj}; i, l \in \{1, 2, \dots, m\}; j \in N, & (2) \\ & y_{ij} + p_{ik} \leq y_{ik} + Lx_{ijk}, & i \in \{1, 2, \dots, m\}; j, k \in N, & (3) \\ & y_{ik} + p_{ij} \leq y_{ij} + L(1 - x_{ijk}), & i, j \in \{1, 2, \dots, m\}; j \in N, & (4) \\ & y_{ij} \geq 0, & i \in \{1, 2, \dots, m\}; j \in N, \\ & x_{ijk} \in \{0, 1\}, & i \in \{1, 2, \dots, m\}; j, k \in N, \end{aligned}$$

where $L \geq \sum_{i=1}^m \sum_{j \in N} p_{ij}$.

Constraint (1) ensures that $C_{\max}$ is no smaller than the completion time of the last task for each job j . The task processing order for each job j is modeled by constraint (2). Constraints (3) and (4) model the requirement that jobs j and k are not processed simultaneously on machine M_i . If $x_{ijk} = 1$, then constraint (3) requires that job j completes before job k starts. Further, constraint (3) holds for any reasonable values of y_{ij} and y_{ik} . The reverse is true if $x_{ijk} = 0$. These types of constraints were first proposed by Manne [24].

An alternative formulation is as a graph problem with two types of directed arcs: conjunctive (standard) and disjunctive [25]. The conjunctive arcs model the processing order for the jobs, while the disjunctive arcs represent the possible job schedules for the machines. An appropriate selection from the set of disjunctive arcs provides a specific machine processing schedule. Then, the remaining disjunctive arcs are removed from the graph. In the resulting graph, the longest path is equal to the makespan corresponding to the machine processing schedule. This concept is illustrated by the following example.

Example 1. There are three machines and three jobs. The machine processing order for Job 1 is M_1, M_2, M_3 , for Job 2 is M_2, M_3, M_1 , and for Job 3 is M_2, M_3 . The processing times are $p_{11} = 3, p_{21} = 5, p_{31} = 1, p_{12} = 2, p_{22} = 4, p_{32} = 4, p_{23} = 4$, and $p_{33} = 2$. The objective is to minimize the makespan.

The disjunctive graph associated with Example 1 is presented in Fig. 1. Each node (i, j) corresponds to the operation for job j on machine M_i . The three solid paths from source S to sink T represent the machine order for each of the jobs. As an example, $S - (2, 2) - (3, 2) - (1, 2) - T$ shows that job 2 is first processed on M_2 , then on M_3 , and finally on M_1 . The sets of dotted arcs form cliques (subgraphs where every pair of nodes is connected by an arc). Each clique corresponds to a machine. Moreover, a selection of a subset of arcs that form a path through the clique is a decision

regarding the job processing order on that machine. The number next to an arc is the length of the arc which corresponds to the processing time of the job at the tail of the arc. For instance, because $p_{23} = 4$, the arcs $((2, 3), (2, 2))$, $((2, 3), (2, 1))$, and $((2, 3), (3, 3))$ all have a distance of four.

Suppose we process the jobs on M_1 in the order $1 \rightarrow 2$, on M_2 in the order $2 \rightarrow 3 \rightarrow 1$, and on M_3 in the order $2 \rightarrow 3 \rightarrow 1$. Then, the resulting graph is shown in Fig. 2. The longest path in this graph is represented by a heavy line. The sum of the distances on this path, which is 12, is the makespan of the schedule corresponding to our job ordering decisions. The processing schedule for Example 1 is presented in the Gantt chart in Fig. 3. Note that for the given job ordering, no job can start earlier without violating some constraint.

AN EASILY SOLVED CASE

One of the few versions of this problem where an optimal solution can be found quickly is when there are only two machines, M_1 and M_2 , and the objective is to minimize the makespan [26]. For this problem, there are four types of jobs:

- A: jobs that are processed only on M_1 ;
- B: jobs that are processed only on M_2 ;
- G: jobs that are first processed on M_1 and then on M_2 ;
- H: jobs that are first processed on M_2 and then on M_1 .

The makespan is minimized when the processing time on the bottleneck machine is minimized. Thus, it is important to start both machines as quickly as possible and to prevent idle time caused by one machine waiting for the other to finish a specific job. Consequently, an optimal solution is to process on M_1 first the G jobs, then the A jobs, and finally the H jobs. On M_2 , the H jobs should be processed first, followed by the B jobs, and finally the G jobs (Fig. 4). The only issue that still needs resolution is how the jobs are processed within a given job type. Since the A jobs are only processed on

Figure 1. Disjunctive graph for Example 1.

one machine, the order does not affect the completion time. Consequently, any order is optimal. The same is true for the B jobs. However, order may be important for the G and H jobs. As an example, supposed that all jobs were type G . Then, the problem is a two machine flow shop problem, where the optimal solution is to use Johnson's Algorithm [27]. The order generated by Johnson's Algorithm is optimal for the G and H jobs, where the first machine for the H jobs is M_2 .

Another two-machine problem that can be solved quickly is a stochastic version where the processing time of a job on a machine is generated from a unique exponential distribution, and the objective is to minimize the expected completion time [14].

Figure 4. Optimal job order for two-machine makespan problem.

Surprisingly, when a job can be interrupted and then resumed later, called *preemption*, the problem is intractable [28].

HEURISTICS

Because the job shop scheduling problem is so difficult to solve, there is a large literature that examines approximate methods, called

Figure 2. Graph for Example 1 with scheduling decisions.

Figure 3. Gantt chart for Example 1.

heuristics, that find good but not necessarily optimal solutions. The most important of these methods is the *shifting bottleneck heuristic* [7]. This heuristic finds the machine that is most likely to become the bottleneck in a current partial schedule. Each job on an unscheduled machine is assigned a release date and due date (desired completion time). Then, each of these one-machine scheduling problems is solved where the objective is to minimize the job tardiness. While this one-machine problem is intractable (see **Single Machine Scheduling**), in general, solutions can be found rapidly. The machine with the maximum tardiness is in some sense, the bottleneck machine. As a result, this machine is scheduled. All of the previously scheduled machines are now rescheduled based on the new bottleneck machine schedule. Then, the process is repeated, each time scheduling one new machine, until all machines are scheduled.

The shifting bottleneck heuristic has been extended to solve other versions of the job shop problem. As examples, Balas *et al.* [29] include sequence-dependent setup times (setup time before processing begins depends on the prior task), release dates, and deadlines, and Ivens and Lambrecht [30] consider release and due dates, assembly and splitting of jobs, overlapping processing times, setup times, transportation times, and multiple machines at a work station. As a final example, Mason *et al.* [23] minimize weighted tardiness where constraints include multiple and batching machines (several tasks are processed simultaneously) at a work center, sequence-dependent setup times, and reentrant flows (a job visits a machine more than once).

While the most important heuristic approach is the shifting bottleneck method, there are several other important research directions. One approach is to approximate the movement of the jobs as a fluid flow [31]. Another approach is to use a randomized algorithm [32]. To improve expected performance, a randomized algorithm makes decisions stochastically.

There is also a large literature on meta-heuristic procedures that solve the job shop scheduling problem. Some examples are

tabu search [33], simulated annealing [34], and genetic algorithms [35]. Aarts *et al.* [36] compare these methods with a threshold acceptance procedure. This is a multistart iterative improvement procedure where a random starting solution is selected. Then, the procedure tries to reduce completion times by repeatedly moving to neighboring solutions that are superior.

For many applied settings, jobs have due dates. Because the decision is to determine the order of the jobs on the machines, a literature on dispatching rules has emerged. These rules provide heuristics that specify the order in which the jobs should be processed on a machine. Most rules are based on processing times, completion time, due dates, or some combination of these measures. One standard rule is shortest remaining processing time (i.e., SPT). When several jobs are available for processing, the rule selects the job with the shortest remaining processing time to be scheduled next. This represents an attempt to minimize the WIP costs. This rule works well when the objective is to minimize the total flow time (completion time minus the start time). Variations on SPT include shortest processing time for the current machine and ratios of total processing time remaining to the number of tasks remaining. When the goal is to meet due dates (desired completion times), other dispatching rules such as minimum slack, work better [37]. Most of these rules either consider variations of the slack time or flow time. Typically, these rules are tested via simulation experiments. Researchers that have studied dispatching rules include [9,38–42].

FUTURE DIRECTIONS

One future direction of job shop scheduling is to improve the current solution techniques both for optimal and heuristic methods. With the wide variety of solution techniques available, there is little knowledge about which method to select for a specific instance. A better understanding of the strengths and weaknesses of each method would improve our ability to find a good or optimal solution. Research will also continue to expand the

generality of the models. We need to be able to solve larger and more realistic problems. Another direction is to more carefully consider robust solutions, solutions that are insensitive to changes in the shop floor. Changes could include new jobs entering the system, the canceling of scheduled jobs, machine breakdowns, and processing time deterioration. A final and perhaps most important direction is to embed the job shop problem into the supply chain. This can be done by integrating the job shop problem with other supply chain activities such as the purchase and storage of raw materials, or the distribution and pricing of final products. An emerging area of research examines supply chain scheduling problems where there are multiple agents. These multiagent problems can be studied where the production facility is a job shop. Examples include models where several customers want to use limited job shop capacity or models where suppliers provide parts to the shop.

JUST-IN-TIME/LEAN PRODUCTION SYSTEMS

W.C. BENTON, JR.
Department of Management Sciences,
Fisher College of Business, The Ohio
State University, Columbus, Ohio

INTRODUCTION

In its simplest form, “the manufacturing process” is a process of material flow. The just-in-time (JIT) philosophy is based on the elimination of capacity and inventory waste and removing non-value-added activities in the manufacturing operation. Specifically, JIT is a manufacturing system in which materials that are pulled through the system are delivered at the precise time to each step in the process, just as they are needed. JIT manufacturing is designed to manage the flow of materials, components, tools, and information. *JIT* production is based on planned elimination of all waste and on continuous improvement. In the past 10 years, JIT has been closely associated with *lean production*. Today, the two terms are used interchangeably simply because they represent highly coordinated repetitive high volume manufacturing systems. An organization driven by JIT philosophy can improve profits and return on investment by reducing inventory levels, reducing variability, improving product quality, reducing production and delivery lead times, and reducing setup costs. With JIT, the entire manufacturing system from purchasing to shop-floor management can be measured and controlled. Therefore, the JIT system is a powerful management tool that could easily determine the success or failure of the manufacturing system. Companies following the JIT philosophy often experience increased efficiency and higher service and product quality. The conceptual framework for the JIT philosophy is shown in Fig. 1.

JIT applies primarily to repetitive manufacturing processes in which the same products and components are produced over and over again. The general idea is to establish efficient flow processes (even when the facility uses a job shop or batch process layout) by linking work centers so that there is an even, balanced flow of materials throughout the entire production process, similar to that found in an assembly line. To accomplish this, an attempt is made to reach the goals of driving all inventory buffers toward zero and achieving the ideal lot size of one unit.

For more than three decades, JIT and material requirement plan (MRP) production systems have followed two independent research streams. However, the performance comparison and compatibility of JIT with MRP systems has led to intensive debates among practitioners as well as researchers (see *Materials Requirements Planning, Push and Pull Production Systems*). As the popularity of JIT motivated by the success of Japanese manufacturing firms has grown, numerous global practitioners initiated complete changeovers from the traditional MRP-based methods to JIT methods. For instance, Harley–Davidson and Hewlett–Packard are two of the most popular examples of JIT success testimonials.

There rarely exists a pure JIT production system in practice. Even at Toyota, the inventor of the JIT system, production smoothing is planned by the master production schedule (MPS), and the MRP is followed on the basis of the MPS, using bill of materials (BOM). This type of manufacturing planning has been adopted by most automobile manufacturers. The integration between MRP and JIT in literature reflects the trend toward a more realistic hybrid-manufacturing environment.

The current shift toward the lean manufacturing environment is one of the major motivations for continuous improvement. There is also a strong need to organize the previous JIT studies and provide directions

Figure 1. Conceptual framework for JIT.

for innovative JIT implementations and research focus. Since the JIT philosophy is based on planned elimination of all waste and on continuous improvement of productivity, it must encompass essential elements for successful implementation. The following practices are considered as the essential elements for a successful JIT implementation (Fig. 1):

1. *Uniform Production (also known as heijunka).* This creates a uniform load on each work station through constant daily production and producing the same mix of products each day, using a repeating sequence. Meet demand fluctuations through end-item inventory rather than through fluctuations in production level. Use of a stable production schedule also permits the use of *backflushing* to manage inventory: an end-item's bill of materials is periodically exploded to calculate the usage quantities of the various components that were used to make the item, eliminating the need to collect detailed usage information on the shop floor. See the article titled

Materials Requirements Planning in this encyclopedia.

2. *Quick setup Times.* Aim for short setup times—this can be done through better planning, process redesign, and product redesign. A good example of the potential for improved setup times can be found in the airline industry, where Southwest Airline can turn around 30 full capacity flights per day, between Dallas and Houston. Southwest's efficiency is the result of a team effort using the correct aircraft (container) size, and a coordinated, well-rehearsed process.
3. *Small Lot Sizes.* Reducing setup times allows economical production of smaller lots; close cooperation with suppliers is necessary to achieve reductions in order of lot sizes for purchased raw materials and component parts, since this will require more frequent deliveries.
4. *Short Lead Times.* Production lead times can be reduced by moving work stations closer together, applying group technology and cellular manufacturing concepts, reducing queue length, and

improving the coordination and cooperation between downstream processes; delivery lead times can be reduced through close cooperation with supplying organizations, possibly by inducing suppliers to locate closer to the factory.

5. *Preventive Maintenance.* Use machine and worker idle time to maintain equipment and prevent breakdowns.
6. *Multifaceted Work Force.* Workers should be trained to operate several machines, to perform maintenance tasks, and to perform quality inspections. In general, JIT requires teams of competent, empowered employees who have more responsibility for their own work.
7. *Supplier Development.* All defective items must be eliminated, since there are no buffers of excess parts. A *quality at the source (judoka)* program must be implemented to give workers the personal responsibility for the quality of the work they do, and the authority to stop production when something goes wrong. Techniques such as “JIT lights” (to indicate line slowdowns or stoppages) and “tally boards” (to record and analyze causes of production stoppages and slowdowns to facilitate correcting them later) may be used.
8. *Kanban Production Control.* Use a control system such as a *kanban* (card) pull system (or other signaling system) to convey parts between work stations in small quantities (ideally, one unit at a time). In its largest sense, JIT is *not* the same thing as a Kanban system, and a kanban system is not required to implement JIT (some companies have instituted a JIT program along with an MRP system), although JIT is required to implement a Kanban system and the two concepts are frequently equated with one another. The Kanban system is discussed later. See the article titled **Materials Requirements Planning** in this encyclopedia for a kanban, for a comparison of MRP and JIT.

This entry proceeds in the following order. First, the JIT production system is discussed. Then, the kanban production control system is presented. Third, the JIT purchasing framework is evaluated. Next, the role of culture is discussed. Finally, a critical analysis of the JIT philosophy is conducted.

JUST-IN-TIME PRODUCTION SYSTEM

JIT is focused on waste from overproduction, waste of motion, waste of time, waste of movement, waste due to excessive inventory and the waste resulting from poor quality. JIT is Toyota’s manufacturing philosophy to minimize waste, and the JIT production system is controlled by kanban. An example of the kanban production system is presented later in this article. The kanban-controlled JIT production system has been erected on the basis of the premise of minimizing work-in-process inventories (waste) by reducing or eliminating discrete batches. The reduced lot sizes not only contribute to production efficiency and product quality but also reduce the overall costs associated with production in the JIT manufacturing environment. This proposition holds true only when certain conditions are sustained. According to Monden [1], the success of Toyota’s Kanban-controlled production system is supported by smoothing of production, standardization of jobs, reduction of setup times, improvement of activities, design of machine layout, and automation of processes (automation with human touch). In fact, the JIT production system appears most suitable for repetitive manufacturing environments.

Improvements in the kanban-controlled production systems have followed a pragmatic approach, “continuous improvement”. Therefore, success of the JIT production system must be explained in conjunction with continuous improvement, total quality management, and lean manufacturing [1]. Experience and commitment of the workers on the shop floor to continue to improve performance and methods are the major drivers of the JIT production system.

The JIT production system is not a panacea. As with the MRP system, there are

Figure 2. Reduction in order costs.

also operational problems with the JIT system. In fact, there is a list of reasons why the Toyota manufacturing system may not work for all firms. The reasons include cultural differences, geographical dispersion of suppliers, supplier power, different management styles, etc.

The Toyota's manufacturing system has been viewed in different ways by a variety of researchers. The JIT production system is often called *lean production system*, because it uses less of every resource compared with the conventional mass production system [2]. In general, it is well documented that the JIT production system is a "pull" system as opposed to the conventional MRP push system (see **Materials Requirements Planning, Push and Pull Production Systems**). In the MRP/JIT comparison or integration literature, the pull nature of JIT production system has been discussed extensively [3]. Thus, it is only natural to portray the push/pull debates in conjunction with the MRP/JIT studies. One of the most significant changes in manufacturing over the past 15 years has been the purchasing and supply management function. This significant shift has elevated the importance and profile of purchasing function. JIT production requires significant involvement between Tier 1 suppliers and the buying organization. JIT purchasing is discussed in the following section.

JIT PURCHASING

JIT success requires a close relationship with suppliers, who provide multiple deliveries of high-quality materials. Given the expected precision of JIT production systems, there can be no defective raw materials or component parts. Defective parts or late deliveries will cause severe disruptions in JIT production output. JIT requires buying and supplying organizations to work together to achieve consistent delivery of high-quality materials and component parts.

The function of purchasing is to provide a firm with component parts and raw materials. Purchasing must also ensure that high-quality products are provided on time, at a reasonable price. A comparison of critical elements associated with JIT purchasing and traditional purchasing approaches is as follows:

1. **Reduced Order Quantities.** One of the most crucial elements of the JIT system is small lot sizes. Traditionally, long and infrequent production runs have, in the past, been considered beneficial for the overall productivity of a manufacturing organization. However, long production runs sometimes lead to high levels of raw-material and finished-goods inventories. Large setup times have been the primary motivating factor for longer production runs. The JIT concept reduces setup times and the

associated costs by introducing clever changeover techniques and simpler product designs. This permits more frequent production runs and smaller lot sizes. In turn, the JIT purchasing function becomes responsible for more frequent but smaller orders compared to the traditional case. Under the traditional manufacturing system, suppliers, on average, ship enough materials to cover two months of production; since adopting JIT, the lot size has been trimmed to less than three weeks.

If frequent purchase orders are to be a viable option, traditional inventory theory suggests that order costs be minimal for JIT purchasing to be cost effective. Indeed, the JIT philosophy strives to drive the ordering costs down to a bare minimum. A breakdown of the ordering costs associated with conventional purchasing practices is shown in Fig. 2. Under the JIT purchasing approach, the relationship between the supplier and buyer allows the ordering costs to be reduced to simplify the negotiation and transportation costs. All the intermediate costs are expected to be eliminated once the supplier meets the requirements of a Tier 1 supplier. A substantial decrease in the ordering costs permits a greater number of orders to be placed over shorter intervals.

2. *Frequent and "On-Time" Delivery Schedules.* Supplier performance can be measured more accurately under the JIT purchasing approach compared to

the traditional one. In order to obtain small lot sizes for production, the order quantity size needs to be reduced and corresponding delivery schedules need to be made more frequent. The "on-time" windows have been closing systematically over the years. In the pre-JIT days, "on-time" meant anything arriving up to 12 days ahead of the nominal schedule, and as late as six days. On an average, today's JIT buyers set the window at five days early and two days late. Yet, the surprising fact is that on-time deliveries increased from 62 to 79% in spite of the 11-day reduction in delivery window time.

3. *Reduced Lead Times.* To be able to maintain low inventory levels, it is critical that replenishment lead times be as short as possible. The JIT philosophy inherently attempts to reduce lead times for order completions. Under traditional purchasing practices, the lead time is made up of the following components: paperwork lead time, manufacturing time for supplier, transportation lead time, and time spent on receiving and inspection. A comparison between the JIT approach to lead time and the traditional approach is shown in Fig. 3. Under the JIT system, suppliers are usually associated with the company on a long-term basis. Consequently, it is possible for them to reduce paperwork significantly. Also, the supplier may be able to reduce the manufacturing time because of the guaranteed volumes. As a result of building quality

Figure 3. Reduction in lead time.

into the products, the receiving and inspection time spent by the buyer usually decreases. Replenishment lead times also may be reduced by locating a supplier close to the buying firm's plant.

4. *High Quality of Incoming Materials.* Japanese manufacturers attempt to reduce incoming material inspection as much as possible. In order to eliminate the associated receiving inspection costs, a very high emphasis is placed on the quality of incoming materials under the JIT system.

Xerox provides a good example of the unnecessary resources spent on the incoming inspection of goods in its pre-JIT days. All deliveries from suppliers had to pass through Xerox's Webster plant in upstate New York before they could be redirected to the appropriate plants around the United States.

In some instances, component parts from West Coast suppliers were first shipped to the East Coast for inspection and shipped back to the West Coast manufacturing plants. The JIT approach favors material inspection at the supplier plants. Motivation for the suppliers to furnish high-quality materials is cultivated by long-term agreements and strategic relationships between buyers and suppliers. JIT purchasing, therefore, plays a very critical role in improving product quality at the manufacturing source.

5. *Reliable Suppliers.* Since the JIT system does not provide for buffer stocks, unreliable supply, in terms of delivery

time and quality of incoming material, may lead to frequent problems in production. Consequently, reliability of supply is a critical consideration in the selection of JIT suppliers. Since JIT purchasing has gained popularity within the United States, the purchasing function has been preoccupied with trimming the overall supplier base in quest of so-called superior suppliers. Xerox, for example, reduced its supplier base by nearly 4700 over a period of one year [4]. Ford has reduced its supplier base by nearly 40% since 1980. In the US number of superior suppliers is on the rise as JIT promotes the concept of fewer but better suppliers.

A brief summary of the comparison between the traditional and JIT purchasing approaches is shown in Table 1. JIT purchasing systems are much more difficult to manage. If JIT purchasing systems are not properly implemented and managed, the synergies will be lost and the system will collapse. However, significant advantages are realized if these elements are implemented successfully.

JIT BENEFITS

Implementation of JIT assists in its major objectives of reducing waste from overproduction, improving quality of incoming materials and supplier delivery performance, along with reducing lead times and cost of materials. Some of the critical

Table 1. Comparison between Traditional and Just-in-Time (Lean) Purchasing Approaches

	Traditional Purchasing	JIT Purchasing
Order quantities	Based on trade-offs between ordering and carrying costs	Based on small lot sizes for production
Delivery schedules	Infrequent, primarily because of high ordering costs involved	Frequent because of small lot sizes and low ordering costs
Delivery windows	Relatively wide	Very narrow
Delivery lead times	Relatively long and relaxed	Stringent and reduced significantly
Parts quality	Responsibility of the quality function in the buying organization	Responsibility of supplier
Supplier base	Fairly broad	Considerably smaller

JIT advantages for the manufacturer are discussed below.

1. *Reduced Inventory Levels.* JIT purchasing facilitates reduction in inventory levels and the associated inventory holding costs. Asian firms like Toyota have been able to reduce inventory levels to such an extent that their inventory turnover ratios have gone up to over 60 times per year, compared to corresponding ratios of 5 to 8 reported by most American manufacturers. US manufacturers have been trying to reduce inventory levels by using JIT purchasing techniques. National Cash Register (NCR's) Ithaca plant, for instance, has been successful in reducing its number of days of inventory from 110 to 21 within three years of implementing JIT. However, a strong debate exists as to whether or not manufacturers shift the burden of inventories to suppliers using the guise of JIT. This issue will be addressed later. Reduced inventory levels are indeed one of the benefits of the JIT system, which basically stresses continuous improvement and elimination of waste.
2. *Improved Lead-Time Reliability.* Compared to traditional manufacturing approaches, delivery lead times under the JIT system are considerably shorter. Lead-time reliability is usually much better for JIT systems. This implies higher levels of customer service and lower safety stock requirements for the company. Lower levels of safety stock contribute significantly to reduced working capital requirements for the firm.
3. *Scheduling Flexibility.* JIT emphasizes scheduling flexibility by aiming for reduced purchasing lead times and setup times. Such flexibility prevents confusion in the manufacturing plant and offers unique competitive advantages to manufacturing firms since they are capable of adapting to changes in the environment more quickly.
4. *Improved quality and customer satisfaction.* JIT manufacturing results in improved quality and corresponding levels of higher customer satisfaction. Since high-quality products are critical in achieving a competitive advantage in today's global business world, manufacturers gain immensely by implementing the JIT production control system. High-quality incoming materials result in savings associated with reduced rework and scrap.
5. *Reduced Costs of Parts.* As cooperation and relationships between suppliers and manufacturers build up in a JIT system, so do the opportunities to conduct an extensive value analysis and focus on reducing the cost of parts purchased. A comprehensive JIT progress report indicates that supplier costs were reduced by 11% when they adopted the JIT system in cooperation with their customers. Long-term commitments on the part of the manufacturer allow volume purchases, development of supplier learning curves, and overall productivity increases [4].
6. *Constructive Synergies with Suppliers.* A JIT purchasing program involves close technical cooperation with suppliers. This particularly means the cooperation between manufacturing and design engineers. Because of smaller lot sizes and frequent delivery schedules, suppliers are in a position to receive quick feedback regarding any potential manufacturing or design problems. Also, manufacturing is in a position to implement engineering changes quicker because of the reduced inventory levels. The JIT progress report mentioned above indicates that supplier quality improved by 26% since the JIT system was adopted.

It is well documented that JIT reduces the physical inventory level. Reductions in physical inventory will also have a favorable impact on the following:

- Reduced insurance premiums associated with the storage of inventory.

- Reduced inventory holding costs.
- Reduced labor cost in store rooms and material handling costs.
- Reduced clerical and administrative costs.
- Reduced waste from the manufacturing process.
- Reduced obsolescence costs.
- Reduced depreciation of handling and storage equipment.

Each of the cost savings will result in a leaner, more profitable operation.

THE ROLE OF CULTURE

A crucial issue to be considered is the relevance of culture in the successful implementation of the JIT system in a country. Honda's culture and its focus on group-oriented activities are particularly suitable to the implementation of the JIT production control system in that environment. The need to have harmony in organizations provides for better manufacturer-supplier relationships at Toyota and Honda. Moreover, long-term relationships between supplier and manufacturer are the norm of doing business in Japan. Severance of a business relationship between manufacturer and supplier has a strong stigma associated with it, which both manufacturers and suppliers try to avoid as much as possible.

Within the United States, however, such relationships between manufacturers and suppliers are a little more difficult to cultivate. Traditionally, the business firms in the United States are so short-term oriented that they have their immediate interests in mind. Moreover, the level of employee and supplier commitment to the JIT concept is not as uniform and high as it is in Japan. This does not mean that JIT is not a viable concept in the United States. It is not advisable, however, for US firms to blindly emulate the Japanese JIT approach. In fact, US firms should try and tailor JIT to their needs and circumstances. Some firms in the United States have developed and implemented their own version of JIT under different

names, such as lean, ZIPS (zero inventory production systems), MAN (material as needed), and nick of time. A case study on JIT indicates how Hutchinson Technology (a publicly held company that manufactures a variety of products for computer peripheral and military markets) organized and implemented JIT manufacturing [5]. The major difficulties encountered in the process included the inability of purchasing personnel to make the immense cultural transformation and the lack of resources to effect the change properly. Despite these difficulties, their JIT purchasing program has been successful. Greater geographic separation between supplier and manufacturer in the United States is a major impediment to the implementation process according to the one survey [6]. The survey also indicates that JIT does not imply single sourcing in the United States as it does in Japan. This reflects the reality of the marketplace in the United States and efforts of manufacturers to adjust to it as best as they can.

CRITICAL ANALYSIS OF THE JIT CONCEPT

Most of the testimonials published on JIT systems exalt the simplicity inherent in the system processes and procedures. However, the key issue for a firm in the United States is whether it is simple to implement JIT in an existing manufacturing environment. Does JIT really provide the solution to most manufacturing problems in the United States? It is also worth investigating whether traditional purchasing approaches have been outdated in light of JIT production.

JIT came under intense scrutiny when Japanese manufacturers stormed into the US markets and took away a substantial share from the US automobile industry. Subsequent investigations revealed, much to the relief of US manufacturers, that it was not only the work culture in Japan that provided the Japanese an edge but also the JIT approach to manufacturing management. Many US manufacturers have been in strong pursuit of this manufacturing revolution and manufacturing excellence that JIT was portrayed to bring. Several manufacturing firms

that adopted the JIT approach early include General Motors, Hewlett Packard, Ford, and Xerox. Unfortunately, the excitement about the radically new manufacturing approach, coupled with the romantic version of JIT put forward by many, lulled quite a few manufacturers into believing that JIT would bring instantaneous results for their companies. Too many companies turned to JIT looking for a relatively painless financial surgery that would yield substantial short-term benefits. Over the years, these companies have come to realize the tremendous effort and commitment required to make a JIT system run smoothly.

The radical proponents of JIT manufacturing in the United States during the past three decades, the so-called JIT revolutionaries, are to some extent responsible for this initial misunderstanding. The practitioners painted an extremely romantic picture of JIT emphasizing simplicity and efficiency, along with a state of affairs where employee morale would be high and relations between buyers and suppliers would be completely harmonious. They also called for immediate action and changeover to JIT without really considering the possible ramifications of implementation in the United States. Nor did they convey the message that driving obstacles and impediments out of the system would take serious and substantial effort, commitment, and time.

The pragmatic version of JIT put forth by Japanese authors focuses on the details of the production process. Here the emphasis is on identifying impediments to the smooth flow of materials and innovative techniques to overcome those problems. The Japanese perspective clearly stresses the need for careful and slow implementation, following thorough preparation. It takes time to change attitudes of the workforce and nurture long-term relationships with suppliers.

The transition to JIT has not necessarily been a smooth one for many companies in the United States. But this does not imply that switching from a pure MRP system to a JIT or hybrid system was a mistake for most companies. There are two serious drawbacks with the MRP production control system. First, the master production schedule that

drives MRP is based on estimated customer requirements; and second, MRP's production control system utilizes a "push" system for manufacturing goods. That is, the purchasing function places orders for materials in large lot sizes even though the material may not actually be required, and one work station pushes materials to the next regardless of actual production requirements. Changes in demand estimates or forecasts may allow inventory to pile up in the plant. Very frequent adjustments to the master production schedule make the production system extremely nervous and place enormous pressures on purchasing. However, it must be admitted that MRP is an elegant technique for the requirements of exploding materials for production. This system has increasingly become easier to implement with the advent of sophisticated computing technology. It is not surprising to find some Western manufacturers who still utilize MRP for ordering purchased materials but require that delivery schedules be based on the kanban system and lean concepts. For a more comprehensive discussion, see the MRP entry.

Another critical issue for JIT manufacturers is the variability in product demand. The JIT system seems to work best when its smooth production and low inventory requirements are aimed at meeting a relatively stable product demand. However, demand patterns are not stable for all products. In order to induce a relatively stable demand, companies using JIT manufacturing often consolidate their product lines. They emphasize high quality and low cost of the product, but not variety and availability. This suggests that not all marketing strategies are compatible with the JIT system.

Does this mean that JIT, as a concept, is not particularly suited to manufacturers in the United States? The basic concept is as applicable in the United States as it is in Japan. The JIT system does yield substantial benefits where it has been implemented properly. Undoubtedly, proper implementation of JIT is the key to its success. We have seen the advantages JIT offers to a firm from a purchasing point of view. There are significant benefits to other functional areas as well. However, it should be realized that JIT

is not a panacea for all manufacturing problems and scenarios. A comprehensive study by Krajewski *et al.* revealed that the selection of a production or inventory system can be of less importance than the improvement in the manufacturing environment itself [7]. Keeping this in mind, manufacturers in the United States should evaluate the potential benefits of a JIT system from their own perspective, not from that of the romantic visionaries.

CONCLUSION

JIT has changed the way manufacturing is conducted throughout the world. JIT applies primarily to *repetitive manufacturing* processes in which the same products and components are produced over and over again. JIT is driven by a philosophy of eliminating waste and continuous improvement. Waste results from any activity that adds cost without adding value, such as the unnecessary moving of materials, the accumulation of excess inventory, or the use of faulty production methods that create products requiring subsequent rework. JIT improves profits and return on investment by reducing inventory levels, reducing variability, improving product quality, reducing production and delivery lead times, and reducing other costs. In a JIT system, underutilized (excess) capacity is

used instead of buffer inventories to hedge against problems that may arise. Perhaps one of the most important realities of JIT is the fact that supplying organizations have become an important consideration for the manufacturing function, wherein they should be viewed as partners and not adversaries.

KLIMOV'S MODEL

JOSÉ NIÑO-MORA
Department of Statistics,
Carlos III University of
Madrid, Madrid, Spain

FEEDBACK QUEUEING MODELS FOR TIME-SHARED SYSTEMS

The 1960s witnessed a surge of activity in the development and analysis of feedback queueing models of time-shared computer and communication-network systems, following the introduction of the first such model in Ref. 1. For a pioneering analysis of a queue with feedback see Ref. 2. A time-shared system is meant to provide service to multiple users, by allocating processing resources (e.g., a computing processor or a multiaccess communication channel) in such a way that users experience the illusion that they have continuous and simultaneous access to them. In the single-processor case, this is accomplished by allocating the processor at each time to one user but only for a short period of time, termed a *quantum* of service. If the service requirements of a user's submitted job are satisfied within his allotted quantum of service, the user leaves the system. Otherwise, the job is fed back into the system's queue with its service requirements accordingly updated, to await its next turn of server's attention, according to the *scheduling policy* adopted to decide which job to serve next at each time.

A number of such policies were devised at the time [3–6], which give preferential treatment to short (e.g., interactive) jobs at the expense of long (e.g., noninteractive) jobs. Perhaps the simplest is the *round-robin* policy, whereby an incoming job joins the tail of the queue, where queue position determines the order of service (head-of-the-line first) and, after its allotted service quantum, an incomplete job is fed back to the end

of the queue. Another much-studied policy is the *least attained service* (LAS)—also called *foreground-background* (FB)—rule, which incorporates a priority structure by feeding back incomplete jobs to lower priority queues. More analytically tractable idealized versions of such policies, where the processor's capacity is simultaneously shared by multiple jobs, are obtained by letting the quantum size tend to zero, which gives rise to so-called *processor-sharing* policies. See Ref. 7, Chapter 4 for a review and discussion of these and other models and policies. A multiclass queue under a static priority policy with probabilistic feedback and round-robin within each class is analyzed in Ref. 8.

KLIMOV'S MODEL, RESULTS, EXTENSIONS, AND APPLICATIONS

Such early works were mostly concerned with the *performance analysis* of given scheduling policies, bypassing the more ambitious *performance optimization* problem, which is to design a scheduling policy that optimizes a given performance objective. To quote from Ref. 5:

“No mention has been made above about how a designer of a time-shared system should choose among various possible priority rules. This presupposes some sort of cost criterion. Even when this is agreed upon, general conclusions are difficult. As a consequence, most of the literature either avoids this question entirely or presents voluminous graphs and tables.”

In his seminal paper [9], Klimov addressed the problem of finding a scheduling policy for a multiclass M/G/1 queue with general Bernoulli feedback that minimizes the steady-state, mean-weighted holding cost. In such a model, which encompasses and extends previous queueing models of time-shared systems, a single server is to be dynamically allocated to a finite number n of job classes, labeled by $k \in N \triangleq \{1, \dots, n\}$.

Class k jobs arrive at the system as a Poisson stream with rate λ_k , and have class-dependent i.i.d. generally distributed service times with finite mean $1/\mu_k$ and variance σ_k^2 . Arrival and service-time processes are independent across classes. Upon completion of a class k job, it is fed back to continue further processing as a class l job with probability p_{kl} , for $l \in N$, leaving the system with probability $p_{k0} \triangleq 1 - \sum_{l \in N} p_{kl}$.

Such Markovian feedback probabilities are assumed to be such that, in the absence of further arrivals, a job starting out at any class eventually leaves the system with probability 1. This will be the case if the matrix $\mathbf{I} - \mathbf{P}$ is invertible, where $\mathbf{I}$ is the identity matrix and $\mathbf{P} = (p_{kl})_{k,l \in N}$ is the feedback probability matrix. The total arrival rate $\hat{\lambda}_k$ for each class k is given by the unique solution to the traffic equations

$$\hat{\lambda}_l = \lambda_l + \sum_{k \in N} p_{kl} \hat{\lambda}_k, \quad l \in N.$$

Model parameters are assumed to satisfy the stability condition stating that the traffic intensity, or utilization factor, $\rho \triangleq \sum_{k \in N} \rho_k$ be less than unity, where $\rho_k \triangleq \lambda_k / \mu_k$ is the traffic intensity for class k .

During its stay in the system, a class k job incurs linear holding costs at rate c_k per unit time. Server allocation decisions are made according to an *admissible* scheduling policy, which is required to be (i) *work conserving*, that is, it neither allows the server to sit idle while there are jobs waiting, nor does it affect the total service requirement or the exogenous arrival time of any job; (ii) *nonanticipative* or history-dependent, that is, decisions at any given time can only be based on current or past system information, but not on future information such as future arrival times or remaining service requirements of jobs that have not yet departed; (iii) *ergodic*, that is, they induce on system processes, such as the customers' waiting times or the number in system for each class, steady-state distributions with finite means matching the corresponding sample averages; and (iv) *non-preemptive*, that is, the server allocates its full service capacity to jobs one at a time proceeding uninterruptedly to completion of the job at its current class.

The problem addressed by Klimov [9] was to design an admissible scheduling policy that minimizes the steady-state mean holding cost rate. He established the optimality of a static (priority)-index rule, where a numeric index v_k^* is attached to each class k , and jobs are scheduled by awarding higher nonpreemptive priority [10] to classes with larger index values, breaking ties arbitrarily. Jobs within the same class are served on a first-come first-served (FCFS) basis. Such a result extends to a multiclass M/G/1 queue with feedback the earlier result on optimality of a static index rule (the *cμ-rule*) for the special case without feedback, which had been established in Refs 11, (pp. 84–85) and 12. Klimov further furnished in Ref. 9 a one-pass *adaptive-greedy algorithm* that computes the n index values in n steps, requiring the solution of appropriate linear equation systems.

The approach deployed in Ref. 9 to obtain such results was also ground-breaking, as it did not rely on conventional dynamic programming arguments, which do not lend themselves easily to analyze multidimensional semi-Markov system models with unbounded costs per stage, such as Klimov's model. Instead, Klimov [9] introduced the use of *linear programming* (LP) formulations for optimal queueing scheduling problems, which exploit their special structure, thus pioneering what has later been termed the *achievable performance region approach* (see Ref. 13 and the accompanying discussion). By formulating certain flow balance relations as linear equality constraints on system performance measures, Klimov was able to reformulate the optimal dynamic scheduling problem of concern as a tractable LP problem having $O(n^2)$ linear equality constraints on $O(n^2)$ variables. Then, by exploiting the LP problem's special structure and drawing on LP duality theory, he solved analytically both the LP and the scheduling problem in terms of the index values v_k^* referred to above, which emerge in the solution to the dual LP problem. In Ref. 14, Klimov obtained simpler expressions for the index and further results for a special case of the model in Ref. 9. As for interpretation of the Klimov index v_k^* of class k , it is shown in Ref. 14 to measure the maximum reduction

in expected holding cost per unit expected service time that can be achieved on a single job starting out at class k , in a series of processing stages that ends according to a stopping rule. Hence, a remarkable property of the Klimov index is that it does not depend on the exogenous arrival rates λ_k .

A version of Klimov's problem under the discounted cost criterion, which incorporates job completion rewards, allows the server to remain idle while there are jobs waiting, and does not require the stability condition $\rho < 1$ to hold, is addressed in Ref. 15. The optimality of a modified static index rule is established. Besides considering the non-preemptive case, the analysis is extended to the preemptive case, provided service times are exponentially distributed. This paper further discusses application of the model to flexible manufacturing systems, where the production of multiple part types which may require rework must be scheduled on a single machine. The approach in Ref. 15 draws on earlier work [16] on optimal scheduling of a multiclass M/G/1 queue without feedback under the discounted cost criterion.

A stronger sample-path optimality result for a version of the Klimov model with two classes and exponential service times, which allows general arrival processes, is given in Ref. 17. A further extension of the Klimov model under non-Markovian arrival and service processes given by point processes is presented in Ref. 18.

An extension of the Klimov model under general arrival and service processes, along with a proof of asymptotic optimality of the Klimov index rule in heavy traffic, is given in Ref. 19.

The Klimov index policy has been proposed in Ref. 20 as a heuristic scheduling rule for the more complex problem of scheduling a multiclass, multistation Markovian queueing network. It must be emphasized that Rosberg [20] further introduced relaxed LP formulations for scheduling problems on such networks, which extend Klimov's original LP formulation [9] and furnish tractable bounds on optimal performance. That is the true origin of such LP formulations, which instead appear to have been attributed to latter work [21–23].

An approximate analysis of the Klimov index rule for multiclass multistation queueing networks proposed in Ref. 20 is given in Ref. 24, exploiting the structure of the LP formulation referred to above via approximate work conservation laws.

A recent application of the Klimov model and index rule to the optimal dynamic scheduling of wireless error-prone transmissions is given in Ref. 25.

RELATIONS WITH STOCHASTIC SCHEDULING AND BANDIT MODELS

Besides its original motivation in the context of time-sharing queueing systems, insightful connections can be drawn between Klimov's model and models in the areas of stochastic scheduling and bandit problems. Stochastic scheduling [26] problems are concerned with finding the optimal priority order in which a given set of jobs with random processing requirements is to be processed, where typically all jobs under consideration are present at the start. The simplest such model involves sequencing a set of jobs on a single processor in a nonpreemptive fashion, in order to minimize the expected total linear holding cost incurred. Such a problem was first solved in the special deterministic case in Ref. 27, and in the stochastic processing-time case in Ref. 28. In both cases, the optimal sequencing rule is of index type, being consistent with the $c\mu$ -rule referred to above. More complex stochastic scheduling problems that incorporate deterministic (modeling precedence constraints among jobs) or random feedback of jobs into the system, and which are also solved by index rules, are addressed in Refs 29–34, where Bruno [34] deals with the version of Klimov's model without external arrivals. An extension of the latter model and also of Klimov's model which incorporates random bulk arrivals is the undiscounted branching bandit model introduced in Ref. 35.

A closely related although distinct research area which has evolved with substantial autonomy is that of bandit problems [36]; see also the article titled *Multiarmed Bandits and Gittins Index*. The classic *multiarmed bandit problem* concerns the optimal

sequential selection of a project to engage at each time over an infinite horizon among a collection of stochastic projects, where each project is modeled as a bandit process, that is, a binary-action (active or passive) discrete-time discounted Markov decision process which can only change state and earn rewards when active. After being long considered both computationally and analytically intractable, the problem was first solved in a landmark result by Gittins and Jones [37], using a dynamic priority-index rule based on a dynamic allocation index attached to each project as a function of its state, whose roots can be traced back to Refs 38 and 39. See also Ref. 40 for a presentation and discussion of such a celebrated result.

An extension of the Gittins and Jones result is presented in Ref. 41 for the so-called *arm-acquiring bandit* model, which incorporates random bulk project arrivals, and can hence be seen as a discounted discrete-time version of Klimov's model. Such a model is further extended in Ref. 42 (Chapter 14, Section 11) to a continuous-time semi-Markov setting under Poisson arrivals, and in Ref. 43 under generally distributed branching bandit arrival processes.

The relations between such discounted models and their undiscounted (time average) counterparts are explored in Ref. 44. It is shown that, under stability conditions, the optimal index rule for the arm-acquiring bandit model is asymptotically equivalent to that for its "closed" counterpart (i.e., the corresponding model without arrivals) in the undiscounted limit.

A striking difference between the performance objectives in stochastic scheduling and in bandit problems is that, typically, the former seek to minimize a measure of holding costs incurred, whereas the latter strive to maximize a measure of rewards earned on active projects. In Ref. 45, the *multiarmed tax bandit problem* is introduced, which incorporates a discounted waiting cost objective, and the two types of problems (maximize the rewards earned on active projects and minimize the costs incurred by passive projects) are shown to be equivalent for discounted bandit problems via a simple transformation, which allows use of a

Klimov-like algorithm to compute the Gittins index for discounted arm-acquiring bandits, including the discounted version of Klimov's model [15] as a special case. Such a relation between Klimov's and bandit models is further elucidated in Ref. 46 and more generally in Ref. 44, where it is shown that the Klimov index in Ref. 9 is the undiscounted limit of the Gittins index in the corresponding arm-acquiring bandit model. Also, the optimality of the Klimov index rule is established under preemptive policies assuming exponential service time distributions. The relation between classic and tax bandit problems and the Klimov model is further clarified in Ref. 47 via conservation laws, and more recently in Ref. 48, focusing on performance evaluation under the optimal index rule in the undiscounted case.

A modification of Klimov's index algorithm was introduced in Refs 49 and 50 to compute the index for restless bandits introduced in Ref. 51. See also the review paper [52] and the accompanying discussion.

GENERALIZED CONSERVATION LAWS, PERFORMANCE REGION, ADAPTIVE POLICIES, AND PARALLEL SERVERS

The so-called *achievable performance* region approach to stochastic optimization (see Ref. 13 and the accompanying discussion) seeks to address a problem such as Klimov's by reformulating it as an LP problem in the space of performance measures of concern (e.g., mean waiting times for each class), and then obtain an optimal policy from the latter's solution. As pointed out above, such an approach was in fact pioneered by Klimov himself in his original analysis in Ref. 9, where an LP formulation was presented based on flow balance arguments, and the optimal index rule was obtained from the latter's LP solution via duality theory.

A powerful alternative method for obtaining LP formulations for the region of achievable performance of a multiclass queueing system under admissible scheduling policies, which are required to be work conserving (i.e., no work is created or destroyed), is based on exploiting the

fundamental principle of work conservation. This states that, under work-conserving policies, the unfinished work process $U(t)$, measuring the total remaining service time due to jobs present in the system at each time t , is sample-path invariant. For certain models, the work conservation principle yields so-called *work conservation laws*, which are linear constraints on performance measures characterizing, totally or partially, the achievable performance region. The reader is referred to the article titled **Conservation Laws and Related Applications** in this encyclopedia for a comprehensive discussion and review of such a topic. Early work on conservation laws focused on multiclass queues without feedback. The seminal conservation law of Kleinrock [53,54] was gradually developed [55–59] into the framework of so-called *strong conservation laws* [60], which yields a complete characterization of the achievable performance region in the form of (the base of) a polymatroid, a much studied polyhedron in polyhedral combinatorics introduced in Ref. 61. Thus, the optimality of the $c\mu$ -rule for the corresponding dynamic scheduling problems was shown to be a consequence of the optimality of the greedy algorithm for solving LP problems over polymatroids.

An exact polyhedral characterization of the performance region for Klimov's model under ergodic policies, obtained via the principle of work conservation, was first presented in Ref. 62. The linear constraints characterizing the region of achievable mean delays $\bar{W}^\pi$ consist of: an equality constraint of the form

$$\sum_{k \in N} \rho_k^N \bar{W}_k^\pi = g(N),$$

along with a family of inequality constraints of the form

$$\sum_{k \in S} \rho_k^S \bar{W}_k^\pi \geq g(S)$$

for nonempty subsets $S \subset N$ of customer classes, where the ρ_k^N and ρ_k^S are positive workload coefficients. The resulting polytope is no longer the base of a polymatroid, but that of a new type of polytope, a so-called *extended polymatroid*, which also possesses

strong structural and algorithmic properties, as elucidated in Ref. 63. Further extensions of conservation laws under nonergodic policies are introduced in Ref. 62, which along further developments are used in Ref. 64 to obtain adaptive policies for optimizing nonlinear performance objectives in the Klimov model. The design of optimal adaptive policies for the Klimov model had been previously investigated in Refs 65 and 66.

The axiomatic framework of strong conservation laws for multiclass queues without feedback in Ref. 60 is extended in Ref. 47 to the framework of generalized conservation laws, which have the form indicated above for the Klimov model. Further, in Ref. 47 such a framework is deployed to obtain the polyhedral performance region of the more general branching bandit model [35,43], both under average and discounted performance measures, including as a special case the classic multiarmed bandit problem [36]. A new proof is thus obtained via conservation laws and polyhedral LP methods for the optimality of index policies in such classic problems. The reader is referred to Ref. 67, (Chapter 11) for an accessible textbook account of such methods.

In Refs 68 and 69 the properties of generalized conservation laws and extended polymatroids are further reviewed and developed, including connections with submodularity and the efficient algorithmic treatment of linear side constraints.

For the extension of Klimov's model that incorporates parallel servers, the Klimov index rule is no longer optimal. Yet, Glazebrook and Niño-Mora [70] introduced an LP relaxation over an extended polymatroid obtained from approximate generalized conservation laws, which yields closed-form bounds implying the asymptotic optimality of the rule in the heavy traffic regime.

CONSTRAINED OPTIMIZATION

In some applications of Klimov's model, one or more traffic classes (e.g., interactive traffic in a communication network) may demand more stringent quality of service requirements, which can be modeled via

upper bounds on corresponding performance measures such as mean delays. In the case of a multiclass, single-server, discrete-time queue without feedback under the average cost criterion, Nain and Ross [71] addressed the problem of finding an optimal scheduling rule that minimizes mean linear holding costs subject to a single linear performance constraint. They used a Lagrangian approach to establish the optimality of a stationary policy obtained by randomizing at each time period between two static priority policies, with both such policies and the corresponding probabilities remaining fixed over time. Such a result is extended in Ref. 72 to the discrete-time version of Klimov's problem under a single linear performance constraint, both under discounted and average cost criteria.

The problem of finding an optimal scheduling policy for the branching bandit problem under the average criterion subject to linear performance constraints, and hence for the Klimov model with such constraints as a special case, is addressed in Ref. 22 via LP methods, exploiting the extension to branching bandits of Klimov's LP formulation in Ref. 9. Unlike the LP formulation in Ref. 47, which has $2^n - 1$ constraints on n variables, that in Refs 9 and 22 has $O(n^2)$ constraints on $O(n^2)$ variables. The extended polymatroid structure of the performance region for the Klimov and branching bandit models is exploited in Refs 68 and 69 to design and compute optimal policies subject to linear performance constraints.

PERFORMANCE ANALYSIS

An exact performance analysis for a single-class multiclass M/G/1 queue with Bernoulli feedback is given in the seminal work [2], in the form of the distributions for the number in system and the delay. For the multiclass Klimov model, although it is not explicitly mentioned in Ref. 9, the mean number in system (and hence the mean response time) for each class under any static priority policy can be readily obtained from the linear equation system already given in Ref. 9, by setting to zero the appropriate variables

consistently with the priority ordering of concern. Such a fact appears to have been overlooked, as Simon [73] presents a mean delay analysis for Klimov's model—and some extensions involving preemptions, branching and bulk arrivals—assuming a deterministic feedback structure. In Ref. 74, such analyses are extended to obtain the waiting-time distribution. For the discounted version of Klimov's model and more generally for branching bandits, the results in Ref. 47 via generalized conservation laws allow obtaining the mean discounted number in system for each class by solving a system of n linear equations, where n is the number of classes. For a review of performance analysis results for corresponding models without feedback.

THE FLUID KLIMOV MODEL

Researchers have also investigated deterministic continuous-state fluid versions of Klimov's model, within the area of fluid models of multiclass queueing networks. The first such study is Ref. 75, where it is shown that the Klimov index rule emerges as a myopic solution to the corresponding fluid model, which is a global solution under a certain condition. Connors *et al.* [76] reports on the application of the fluid scheduling model in Ref. 75 to a real-world wafer fab. In Ref. 77, optimality of the index rule is obtained via Pontryagin's maximum principle, under an additional stability condition. The achievable region approach via generalized conservation laws used in Ref. 47 for the discrete-state model is deployed in Ref. 78 to analyze the fluid Klimov model. For further developments in the analysis of optimal server allocation in fluid queueing networks, including applications to Klimov's model, see Ref. 79. An analysis of the optimal control of the fluid Klimov model with side constraints, via LP methods, is presented in Ref. 80.

In this article, we discuss the k -out-of- n system structure, which is a widely used type of redundancy in both industrial and military systems. First, we investigate the binary k -out-of- n systems, where the system and the components can take only two possible states, completely working or totally failed. The multistate k -out-of- n systems and the weighted multistate k -out-of- n systems are also discussed, where the systems and the components can take multiple discrete states. We limit our discussion of these models for the evaluation of system state distribution given the component state distributions. For topics like order statistics and advanced probabilistic analysis of such systems, readers are referred to Arnold *et al.* [1], Bai and Blasch [2], and Hollander and Pena [3].

BINARY k -OUT-OF- n SYSTEMS

Binary k -out-of- n Systems Concepts

The definition of the binary k -out-of- n system is given as follows:

Definition 1. An n -component system is called a binary k -out-of- n :G system if it is working whenever at least k components are working. An n -component system is called a binary k -out-of- n :F system, if it is failed whenever at least k components are failed.

The k -out-of- n system structure is a very popular type of redundancy in fault-tolerant

systems, with wide applications in both industrial and military systems [4]. For example, it may be possible to drive a car with a V8 engine if only four cylinders are firing. However, if less than four cylinders fire, the automobile cannot be driven. Thus, the functioning of the engine may be represented by a 4-out-of-8:G system. The system is tolerant of failures up to four cylinders for minimal functioning of the engine. In a data processing system with five video displays, a minimum of three displays operable may be sufficient for full data display. In this case, the display subsystem behaves as a 3-out-of-5:G system. In a communications system with three transmitters, the average message load may be such that at least two transmitters must be operational at all times or critical messages may get lost. Thus, the transmission subsystem functions as a 2-out-of-3:G system. Systems with spares may also be represented by the k -out-of- n system model. In the case of an automobile with four tires, for example, usually one additional spare tire is equipped on the vehicle. Thus, the vehicle can be driven as long as at least 4-out-of-5 tires are in good condition [4].

From the definition of binary k -out-of- n :G and k -out-of- n :F systems, it can be seen that redundancy is generally built into a k -out-of- n system, since the value of n is usually larger than the value of k . It can also be observed that both series and parallel systems are special cases of the k -out-of- n system. A series system is equivalent to an n -out-of- n :G system, or a 1-out-of- n :F system. And a parallel system is equivalent to a 1-out-of- n :G system, or an n -out-of- n :F system.

There is an equivalence relationship between the k -out-of- n :G system structure and the k -out-of- n :F system structure. On the basis of the definitions of these two types of systems, a k -out-of- n :G system is equivalent to an $(n - k + 1)$ -out-of- n :F system. Similarly, a k -out-of- n :F system is equivalent to an $(n - k + 1)$ -out-of- n :G system. This means

that provided the systems have the same set of component reliabilities, the reliability of a k -out-of- n :G system is equal to the reliability of an $(n - k + 1)$ -out-of- n :F system and the reliability of a k -out-of- n :F system is equal to the reliability of an $(n - k + 1)$ -out-of- n :G system [4].

Reliability Evaluation of Binary k -out-of- n Systems

In this section, we focus on the methods for reliability evaluation of k -out-of- n :G systems. These methods can also be used to evaluate the reliability of a k -out-of- n :F system, first by converting it to its equivalent k -out-of- n :G system. We discuss the reliability evaluation of k -out-of- n systems with identically and independently distributed (i.i.d.) components, and the reliability evaluation of systems with independent components.

Notation:

- n : number of components in the system;
- k : minimum number of components that must work for the k -out-of- n :G system to work;
- p_i : reliability of component i , $i = 1, 2, \dots, n$;
- p : reliability of each component when all components are i.i.d.;
- q_i : unreliability of component i , $q_i = 1 - p_i$, $i = 1, 2, \dots, n$;
- q : unreliability of each component when all components are i.i.d., $q = 1 - p$;
- $R(k, n)$: reliability of a k -out-of- n :G system or probability that at least k out of the n components are working, where $0 \leq k \leq n$ and both k and n are integers;
- $Q(k, n)$: unreliability of a k -out-of- n :G system or probability that less than k out of the n components are working, where $0 \leq k \leq n$ and both k and n are integers, $Q(k, n) = 1 - R(k, n)$.

Reliability Evaluation of Binary k -out-of- n Systems with i.i.d. Components. In a k -out-of- n :G system with i.i.d. components, the

number of working components follows the binomial distribution with parameters n and p . Thus, we have

$$\begin{aligned} & \Pr(\text{Exactly } i \text{ components work}) \\ &= \binom{n}{i} p^i q^{n-i}, \quad i = 0, 1, 2, \dots, n. \end{aligned} \quad (1)$$

The reliability of the system is equal to the probability that the number of working components is greater than or equal to k .

$$R(k, n) = \sum_{i=k}^n \binom{n}{i} p^i q^{n-i}. \quad (2)$$

Equation (2) is an explicit formula that can be used for reliability evaluation of the k -out-of- n :G system with i.i.d. components.

Reliability Evaluation of Binary k -out-of- n Systems with Independent Components. For systems with independent components, the reliability values of different components can be different. Efficient reliability evaluation algorithms for binary k -out-of- n systems with independent components have been provided by Barlow and Heidtmann [5] and Rushdi [6], as follows:

$$\begin{aligned} R(k, n) &= p_n \cdot R(k-1, n-1) \\ &\quad + q_n \cdot R(k, n-1). \end{aligned} \quad (3)$$

The boundary conditions are

$$\begin{aligned} R(0, n) &= 1, \quad \text{for } n \geq 0, \\ R(k, n) &= 0, \quad \text{for } 0 \leq n < k. \end{aligned} \quad (4)$$

The Binary-Weighted k -out-of- n Systems

Wu and Chen generalized the binary k -out-of- n system models into the binary-weighted k -out-of- n models [7].

Definition 2. In a binary-weighted k -out-of- n system, component i carries a weight of w_i , $w_i > 0$ for $i = 1, 2, \dots, n$. The system works if and only if the total weight of working components is at least k , a prespecified value.

The “weight” here means the contribution of the component. In the binary-weighted system, the component with higher contribution

to the system has a higher “weight.” The component with lower contribution to the system has a lower “weight.” For example, a power generator with a higher output capacity has a larger “weight.”

A recursive equation is provided by Wu and Chen [7]. In the following, $R_w(i, j)$ represents the probability that a system with j components can output a total weight of at least i . Then, $R_w(k, n)$ is the reliability of the weighted k -out-of- n :G system. The following recursive equation can be used for reliability evaluation of such systems:

$$R_w(i, j) = p_j R_w(i - w_j, j - 1) + q_j R_w(i, j - 1), \quad (5)$$

which requires the following boundary conditions:

$$R_w(i, j) = 1, \quad \text{for } i \leq 0, \quad j \geq 0, \quad (6)$$

$$R_w(i, 0) = 0, \quad \text{for } i > 0. \quad (7)$$

When $w_j = 1$ for $1 \leq j \leq n$, the binary-weighted k -out-of- n model is reduced to the regular k -out-of- n system model. Chen and Yang developed a two-stage weighted- k -out-of- n system model with components in common, as well as the reliability evaluation algorithm [8]. Levitin and Lisnianski presented a reliability optimization approach for weighted voting systems [9].

MULTISTATE *k*-OUT-OF-*n* SYSTEMS

Multistate k -out-of- n System Concepts

Many practical components and systems have more than two different performance levels. For example, a power generator in a power station can work at full capacity, which is its nominal capacity, say 10 MW, when there are no failures at all [10]. Certain type of failures can cause the generator to be completely failed, while other failures will lead to the generator working at a reduced capacity say at 4 MW. A component with multiple failure modes can also be considered to be a multistate component [11–13]. Based on the theory of binary coherent systems [14], many system structures, such as series-parallel structure, k -out-of- n structure, and

network structure, have been extended from the binary cases to the multistate cases by allowing the components and the systems to take more than two possible states [4,15–19]. With multistate models, we can deal with reliability issues of engineering systems more accurately, and would be able to answer more operations related questions.

When a component may experience more than two possible states, its state may be represented by a continuous random variable or a discrete random variable. In this article, we adopt the discrete assumption. Each component and the system may experience $M + 1$ possible states represented by $0, 1, 2, \dots, \text{and } M$, where 0 denotes the worst state and M (a positive integer) denotes the best state.

El-Newehi *et al.* [20] defined the first multistate k -out-of- n system model, where the system state was defined as the state of the k th best component. In another word, for the system to be in state j or above, there should be at least k components in state j or above. That is, the k value is the same with respect to all states. Boedigheimer and Kapur [21] defined the multistate k -out-of- n model from the perspective of lower and upper boundary points, and their definition is actually consistent with that by El-Newehi *et al.* Huang *et al.* [22] proposed the generalized multistate k -out-of- n :G system model, where there can be different k values with respect to different states. In the following two definitions, $\phi(\mathbf{x})$ is the structure function of the system, that is, it denotes the state of the system as a function of the component state vector $\mathbf{x}$.

Definition 3. An n -component system is called a generalized multistate k -out-of- n :G system if $\phi(\mathbf{x}) \geq j$ ($1 \leq j \leq M$) whenever there exists an integer value l ($j \leq l \leq M$) such that at least k_l components are in state l or above. In addition, if we have $k_1 \leq k_2 \leq \dots \leq k_M$, the system is called an increasing multistate k -out-of- n :G system and if we have $k_1 \geq k_2 \geq \dots \geq k_M$, the system is called a decreasing multistate k -out-of- n :G system.

Zuo and Tian [23] proposed the definition of the generalized multistate k -out-of- n :F system, which is the mirror image of the

corresponding multistate *k*-out-of-*n*:G system defined in Definition 3.

Definition 4. An *n*-component system is called a generalized multistate *k*-out-of-*n*:F system if $\phi(\mathbf{x}) < j$ ($1 \leq j \leq M$) whenever the states of at least k_l components are below l for all l such that $j \leq l \leq M$.

Reliability Evaluation of the Multistate *k*-out-of-*n* Systems

Notation:

- M : the maximum state level of a multistate system and its components;
- x_i : state of component i , $x_i = j$ if component i is in state j , $0 \leq j \leq M$, $1 \leq i \leq n$;
- $\mathbf{x}$: an n -dimensional vector representing the states of all components, $\mathbf{x} = (x_1, x_2, \dots, x_n)$;
- $\phi(\mathbf{x})$: state of the system, $0 \leq \phi(\mathbf{x}) \leq M$;
- k_j : the k value with respect to level j of a generalized multistate *k*-out-of-*n* system;
- $\mathbf{v}_j$: a minimal cut vector to level j of an increasing multistate *k*-out-of-*n*:F system: $\phi(\mathbf{v}_j) < j$ and $\phi(\mathbf{x}) \geq j$ for all $\mathbf{x} > \mathbf{v}_j$;
- $r_{s,j}$: $\Pr(\phi(\mathbf{x}) = j)$;
- $\mathbf{k}$: the $\mathbf{k}$ vector of a generalized multistate *k*-out-of-*n* system, $\mathbf{k} = (k_1, k_2, \dots, k_M)$;
- $p_{n,j}$: the probability of component n in state j ;
- $\mathbf{k}^j$: the generated $\mathbf{k}$ vector when component n is in state j .

For any generalized multistate *k*-out-of-*n*:G system given in Definition 3, there is an equivalent generalized multistate *k*-out-of-*n*:F system given in Definition 4. The reliability evaluation of a generalized multistate *k*-out-of-*n*:G system can be performed via its equivalent generalized multistate *k*-out-of-*n*:F system.

Before presenting the algorithms, the definition of nominal increasing multistate *k*-out-of-*n*:F system proposed in Ref. 23 needs be introduced.

Definition 5. A nominal increasing multistate *k*-out-of-*n*:F system is the same as an increasing multistate *k*-out-of-*n*:F system except that the probability of a component in all possible states may be less than 1.

The probability for the state of a generalized multistate *k*-out-of-*n*:F system to be below j can be calculated through a generated nominal increasing multistate *k*-out-of-*n*:F system [23]. Thus, the following discussion is focused on the increasing case.

The recursive function in the algorithm is denoted by $Q(m, N, \mathbf{k}, \mathbf{p})$, where $m + 1$ is the number of possible states of the nominal increasing multistate *k*-out-of-*n*:F system, N is the number of components of the nominal increasing multistate *k*-out-of-*n*:F system, $\mathbf{k}$ is the characteristic vector of the nominal increasing multistate *k*-out-of-*n*:F system where $\mathbf{k} = (k_1, k_2, \dots, k_m)$, and $\mathbf{p}$ is the probability vector of the nominal increasing multistate *k*-out-of-*n*:F system where $\mathbf{p} = (p_0, p_1, \dots, p_m)$ [23].

The recursive function $Q(m, N, \mathbf{k}, \mathbf{p})$ is designed to represent the probability for the system to be in state “0” of the nominal increasing multistate *k*-out-of-*n*:F system with $m + 1$ possible states, totally N components, vector $\mathbf{k}$, and probability vector $\mathbf{p}$. Thus, to calculate the probability for the state of a generalized multistate *k*-out-of-*n*:F system to be below j , we can first transform it into a nominal increasing multistate *k*-out-of-*n*:F system to state j and to do the calculation using the recursive algorithm.

The procedure of the recursive algorithms is as follows:

$$Q(m, N, \mathbf{k}, \mathbf{p}) = \sum_{i=k_1}^{k_2-1} \binom{N}{i} p_0^i \cdot \times Q(m-1, N-i, \dot{\mathbf{k}}, \dot{\mathbf{p}}) + Q(m-1, N, \ddot{\mathbf{k}}, \ddot{\mathbf{p}}), \quad (8)$$

where $\dot{\mathbf{k}} = (k_2 - i, k_3 - i, \dots, k_m - i)$, $\dot{\mathbf{p}} = (p_1, p_2, \dots, p_m)$, $\ddot{\mathbf{k}} = (k_2, k_3, \dots, k_m)$, and $\ddot{\mathbf{p}} = (p_0, p_1 + p_2, p_3, \dots, p_m)$. The boundary condition for the recursive algorithm is

$$Q(1, N, \mathbf{k}, \mathbf{p}) = \sum_{i=k_1}^N \binom{N}{i} p_0^i \cdot p_1^{N-i}. \quad (9)$$

From Equations (8) and (9), we can see that this algorithm is actually recursive on the parameter m , not on the number of components N . Therefore, we can apply the recursive algorithm to large systems including a large number of components, without leading to exponential growth of computation time.

The following example is used to illustrate the recursive algorithm for increasing multistate k -out-of- n :F systems described in this section.

Example 1. We consider an increasing multistate k -out-of- n :F system with 10 i.i.d. components and 4 possible states, that is, $n = 10$ and $M = 3$. The $\mathbf{k}$ vector is $\mathbf{k} = (k_1, k_2, k_3) = (3, 6, 8)$. The state distribution of components is $\mathbf{p} = (0.1, 0.3, 0.4, 0.2)$.

To calculate $\Pr(\phi(\mathbf{x}) < 3)$, we get a nominal increasing multistate k -out-of- n :F system to state 3, with $m = 1, N = 10, \mathbf{k} = (k_3) = 8$, and $\mathbf{p} = (p_0 + p_1 + p_2, p_3) = (0.8, 0.2)$. Using the recursive algorithm, the value $\Pr(\phi(\mathbf{x}) < 3)$ is equal to $Q(m, N, \mathbf{k}, \mathbf{p})$, which is 0.6778.

To calculate $\Pr(\phi(\mathbf{x}) < 2)$, we get a nominal increasing multistate k -out-of- n :F system to state 2, with $m = 2, N = 10, \mathbf{k} = (k_2, k_3) = (6, 8)$, and $\mathbf{p} = (p_0 + p_1, p_2, p_3) = (0.4, 0.4, 0.2)$. Using the recursive algorithm, the value $\Pr(\phi(\mathbf{x}) < 2)$ is equal to $Q(m, N, \mathbf{k}, \mathbf{p})$, which is 0.1523.

To calculate $\Pr(\phi(\mathbf{x}) < 1)$, we get a nominal increasing multistate k -out-of- n :F system to state 1, with $m = 3, N = 10, \mathbf{k} = (k_1, k_2, k_3) = (3, 6, 8)$, and $\mathbf{p} = (p_0, p_1, p_2, p_3) = (0.1, 0.3, 0.4, 0.2)$. Using the recursive algorithm, the value $\Pr(\phi(\mathbf{x}) < 1)$ is equal to $Q(m, N, \mathbf{k}, \mathbf{p})$, which is 0.0308.

We can get the probability of the system at each individual state $r_{s,0} = 0.0308, r_{s,1} = 0.1214, r_{s,2} = 0.5255, r_{s,3} = 0.3222$

The algorithm presented above is for evaluating multistate k -out-of- n systems with i.i.d. components [23]. Tian *et al.* extended this algorithm and developed a method for evaluating multistate k -out-of- n

systems with independent components [24,25]. A bounding approach was also proposed for estimating the reliability of multistate k -out-of- n systems in a much shorter time [26]. Amari *et al.* developed a more efficient algorithm for reliability evaluation of multistate k -out-of- n systems with i.i.d. components [27]. Tian *et al.* also proposed another practical model for multistate k -out-of- n systems, and an algorithm for the reliability evaluation [25].

MULTISTATE-WEIGHTED k -OUT-OF- n SYSTEMS

In the binary-weighted k -out-of- n :G system model discussed in the section titled “The Binary-Weighted k -out-of- n Systems,” the weight of the system is the sum of the weights of all working components. When a component is failed, its contribution to the system is zero.

In a multistate context, a component may be in different states. When it is in a different state, it may have a different contribution to the system. When it is completely failed, its contribution to the system is zero. Suppose there are n components in a system, each component may be in $M + 1$ states: $0, 1, 2, \dots, M$, and component i , when in state j , has a weight value of w_{ij} . In the multistate-weighted k -out-of- n :G model to be covered in this section, every component in every possible state has certain contribution to the system’s performance. The formal definition of Model I of the multistate-weighted k -out-of- n :G system is given below [28].

Definition 6. The system is in state j or above if the total weight of all components is equal to or greater than k_j , a prespecified value.

Let ϕ be the structure function of the system representing the state of the system and W the total weight of all components. Then, this definition means $\Pr \phi \geq j = \Pr W \geq k_j$. Since state 0 is the worst state of the system, we have $\Pr \phi \geq 0 = 1$.

According to Definition 3, for the system state to be not lower than a given value j , the

number of components whose states are not lower than j must be at least k_j , a prespecified value. In this definition, the components whose states are below j do not make any contribution for the system to be in state j or above. On the basis of this idea, Li and Zuo define another model of the multistate-weighted k -out-of- n :G system [28]. In the new model (referred to as *Model II* below), for the system to be in state j or above, the sum of the weights of only those components, whose states are in state j or above must be not less than k_j , a prespecified value. The difference between Model I presented above and Model II to be presented next is whether the components whose states are below j are making any contribution for the system to be in state j or above. The formal definition of Model II is given below.

Definition 7. The system is in state j or above if the total weight of the components in state j or above is equal to or greater than k_j , a prespecified value.

Let ϕ be the structure function of the system and W_j be the sum of the weights of the components whose states are j or above. We then have $\Pr \phi \geq j = \Pr W_j \geq k_j$ based on Model II.

Example 2. Consider a conveyor belt set, in which several conveyors work together in parallel. During the life of a conveyor, its state will deteriorate from perfect to failed. When its state degrades, it cannot work under the full load any more. That means corresponding to different states, it has different weights. When we require that in the set, the total drive of all the conveyors to be at least 100 KW to transport coal no matter what the state of each conveyor is, it is an multistate-weighted k -out-of- n system Model I. If we require that in the set, the total drive generated by the conveyors which still can work under full load to be at least 100 KW, it is the multistate-weighted k -out-of- n system Model II.

The reliability evaluation algorithms for the multistate-weighted k -out-of- n system models were presented in Ref. 28. Li and Zuo

also developed an optimal design approach for multistate-weighted k -out-of- n systems based on component design [29].

CONCLUDING REMARKS

The k -out-of- n structure is a very flexible redundancy structure, and has been widely used in many systems. Meanwhile, in many real applications, components and systems might have multiple states. "Multiple states" of a component or system might be interpreted as multiple levels of performance, multiple functions, multiple levels of benefits, or multiple failure modes. The multistate k -out-of- n system models reported in this article enable us to model multiple levels of k -out-of- n requirements of the system. The reliability evaluation algorithms have been presented for efficient performance evaluations of the k -out-of- n system models. A key future work is to do case studies of practical systems with multiple levels of k -out-of- n requirements. It is also important to develop more general models for more general and complex situations.

LAGRANGIAN OPTIMIZATION FOR LP

INTRODUCTION

In many practical applications, there exists a need for repeatedly solving large-scale *linear programming* (LP) problems, especially when such LPs arise as subroutines in a branch-and-bound framework or other polyhedral schemes. It has been amply demonstrated in the literature that solving large-scale linear programs via traditional approaches such as simplex-based algorithms or even interior point methods can sometimes be computationally cumbersome, particularly for cases where the coefficient matrix is dense and ill-conditioned (see Ref. 1, as well as the computational experience in Ref. 2). In such instances, a *Lagrangian optimization* approach can prove to be a very useful tool. Early work related to this approach appeared in Ref. 3, and since then there have been numerous developments in this field, particularly geared toward applying Lagrangian techniques for solving nonlinear and integer programming (IP) problems [1,4–7].

In this article, we focus on developing the Lagrangian optimization approach for solving LP problems. To motivate this methodology, consider the following generic linear program:

$$P: \text{Minimize } \{c^T x \mid Ax \geq b, Cx \geq d, x \geq 0\}, \quad (1)$$

where, following standard notation, $x \in \mathbb{R}_+^n$, $A \in \mathbb{R}^{p \times n}$, $C \in \mathbb{R}^{q \times n}$, $b \in \mathbb{R}^p$, and $d \in \mathbb{R}^q$.

Now, suppose that the set of constraints $Ax \geq b$ are “complicating” constraints, and thus, removing these constraints ensures that this modified problem can be solved fairly easily in comparison to the original Problem P. In a Lagrangian scheme, these complicating constraints are “relaxed” by weighting them with (nonnegative) multipliers $\pi \in \mathbb{R}_+^p$ to obtain the following *Lagrangian relaxation* (LR_π) of Problem P:

$$LR_\pi: \text{Minimize } \{c^T x + \pi^T(b - Ax) \mid Cx \geq d, x \geq 0\}. \quad (2)$$

Remark 1. To be precise, LR_π , as defined in Equation (2), is the *Lagrangian relaxation of Problem P relative to $Ax \geq b$ and a conformable vector $\pi \geq 0$* . For this Lagrangian relaxation to be computationally superior (in comparison to the original Problem P), the remaining constraints $Cx \geq d$ must admit an easy-to-find closed form solution or retain considerable special structure which can be exploited in solving the problem. Examples of such constraints include simple variable upper bounds, flow-balance constraints, block diagonal structures, certain types of inventory constraints, or generalized upper bounding constraints. For detailed examples, we refer the reader to Ref. 5.

In LR_π , notice that the (nonpositive) slack variables of the constraints $Ax \geq b$ have been appended to the objective function of Problem P, weighted with the nonnegative vector π , and moreover, the feasible region has been relaxed by eliminating the complicating constraints. The constraints $Ax \geq b$ are said to have been “dualized,” and the nonnegative weights π used to dualize the complicating constraints are commonly referred to as *Lagrange multipliers*. Given Equation (2), the following propositions hold true trivially.

Proposition 1. *The feasible region of P is a subset of the feasible region of LR_π .*

Proof. The result follows by virtue of relaxing the complicating constraints.

Proposition 2. $v[\text{LR}_{\pi}] \leq v[\text{P}]$, where $v[\cdot]$ denotes the optimal objective function value for any Problem $[\cdot]$.

Proof. Given any $\bar{\pi} \in \mathbb{R}_+^p$, and any solution $\bar{x}$ feasible to Problem P, note that the objective function value of Problem $\text{LR}_{\bar{\pi}}$ is lesser than the objective function value of Problem P; that is,

$$v[\text{LR}_{\bar{\pi}}] \leq c^T \bar{x} + \bar{\pi}^T (b - A\bar{x}) \leq c^T \bar{x}.$$

This inequality, along with Proposition 1, yields the required result.

Using Propositions 1 and 2, we know that for any given $\pi \in \mathbb{R}_+^p$, the optimal solution to Problem LR_{π} provides a valid *lower bound* on Problem P, and this lower bound clearly depends on the value of the Lagrange multipliers $\pi \geq 0$ used in dualizing the complicating constraints. Hence, to obtain the *best* (or *largest*) lower bound for a minimization problem, an appropriate choice of Lagrange multipliers can be realized by *maximizing* LR_{π} over all $\pi \geq 0$, which yields the following *Lagrangian dual* (LD) problem:

$$\text{LD: Maximize } \{\text{LR}_{\pi} \mid \pi \geq 0\}, \quad (3)$$

where LR_{π} is given by Equation (2). It is worth noting here that LR_{π} is a problem in the original variables x , whereas LD is a problem in the so-called “dual space” of the Lagrange multipliers π .

Remark 2. The procedure outlined above for constructing the Lagrangian dual can be easily extended for the case of complicating *equality* constraints as well. If the complicating constraints in Problem P are given by $Ax = b$, then we can equivalently represent this as *two* sets of constraints, $Ax \geq b$ and $-Ax \geq -b$, and associate (conformable) Lagrange multipliers $\lambda \geq 0$ and

$\mu \geq 0$ for respectively dualizing these complicating constraints to obtain:

$$\text{LR}_{\lambda, \mu}: \text{Minimize } \left\{ c^T x + \lambda^T (b - Ax) + \mu^T (-b + Ax) \mid Cx \geq d, x \geq 0 \right\}, \quad (4)$$

which can be rewritten as the equivalent problem:

$$\text{LR}_{\pi}: \text{Minimize } \left\{ c^T x + \pi^T (b - Ax) \mid Cx \geq d, x \geq 0 \right\}, \quad (5)$$

where $\pi \equiv \lambda - \mu$. In this case, π is the difference of two nonnegative quantities and is therefore *unrestricted in sign*. Hence, Lagrange multipliers associated with equality constraints need not be nonnegative for LR_{π} to provide a valid lower bounding relaxation to Problem P.

The remainder of this article is organized as follows: In the section titled “Properties of the Lagrangian Dual”, several propositions and theorems that elucidate the properties of the Lagrangian optimization approach and characterize the Lagrangian dual are presented, followed by an illustrative example. Next, in the section titled “Solution Methodologies For The Lagrangian Dual,” the solution methodologies are described, and finally, the section titled “Extensions and Conclusions” briefly presents some extensions of the Lagrangian approach to integer programs and some concluding remarks.

PROPERTIES OF THE LAGRANGIAN DUAL

In this section, we prove some important results that characterize the properties of the Lagrangian dual and provide some interesting insights that relate the Lagrangian approach to classical LP duality theory.

Definition 1. For any $\pi \geq 0$, an optimal solution to Problem LR_{π} , denoted x_{π} , is called a *Lagrangian solution*.

Theorem 1. Let x_π be a Lagrangian solution corresponding to some $\pi \geq 0$. If x_π satisfies the following conditions:

- (i) $Ax_\pi \geq b$, and
- (ii) $\pi^T(b - Ax_\pi) = 0$,

then x_π is optimal to Problem P.

Proof. As x_π is a Lagrangian solution, we get

$$\begin{aligned} v[\text{LR}_\pi] &= c^T x_\pi + \pi^T(b - Ax_\pi) \\ &\leq c^T x + \pi^T(b - Ax), \quad \forall x \in \{Cx \geq d, x \geq 0\} \\ &\leq c^T x + \pi^T(b - Ax), \\ &\quad \forall x \in \{Ax \geq b, Cx \geq d, x \geq 0\} \\ &\leq \text{minimum} \{c^T x \mid Ax \geq b, Cx \geq d, x \geq 0\} \\ &= v[\text{P}]. \end{aligned}$$

Now, using condition (ii), set $\pi^T(b - Ax_\pi) = 0$ in the above inequality, to get

$$v[\text{LR}_\pi] = c^T x_\pi \leq v[\text{P}].$$

But, from condition (i), we know that x_π is also feasible to $Ax \geq b$, and as Problem P is a minimization problem, this results in

$$v[\text{LR}_\pi] = c^T x_\pi \geq v[\text{P}].$$

Hence proved.

So far, we have proved that a Lagrangian solution, which is feasible to the complicating constraints and satisfies “complementary slackness” conditions is also optimal to Problem P. Continuing in the same vein, Theorem 2 and the subsequent corollaries characterize other important properties of the Lagrangian dual, thereby providing the necessary framework for relating Lagrangian duality with traditional LP duality theory. The main crux of the argument lies in proving that the optimal objective function values of Problem LD and Problem P are equal, and furthermore, the Lagrange multipliers obtained from the optimal solution to Problem LD are indeed the same as the optimal dual variables associated with the complicating constraints

obtained by solving Problem P using standard LP techniques.

Theorem 2. $v[\text{P}] = v[\text{LD}]$.

Proof. Consider,

$$\begin{aligned} v[\text{LD}] &= \text{maximize} \{ \text{LR}_\pi \mid \pi \geq 0 \} \\ &= \text{maximize}_{\pi \geq 0} \left\{ \min \left\{ c^T x + \pi^T(b - Ax) \right. \right. \\ &\quad \left. \left. \mid Cx \geq d, x \geq 0 \right\} \right\}, \\ &= \text{maximize}_{\pi \geq 0} \left\{ \min \left\{ c^T x + \pi^T(b - Ax) \right. \right. \\ &\quad \left. \left. \mid x \in \{x^1, x^2, \dots, x^I\} \right\} \right\}, \end{aligned}$$

where $x^i, \forall i = 1, \dots, I$, are the *extreme points* of $Cx \geq d, x \geq 0$.

Note: For notational ease, we have assumed here that $Cx \geq d, x \geq 0$ is a nonempty *polytope*; that is, a closed and bounded polyhedron, and can be defined purely in terms of its extreme points with no recession directions. A very straightforward extension of the arguments presented here is applicable for the more general case.

Hence,

$$v[\text{LD}] = \text{maximize } v[\text{LR}_\pi] \quad (6a)$$

$$\begin{aligned} \text{subject to : } & v[\text{LR}_\pi] \leq c^T x^i \\ & + \pi^T(b - Ax^i), \quad \forall i = 1, \dots, I; \end{aligned} \quad (6b)$$

$$\pi \geq 0. \quad (6c)$$

Note that Problem (6a)–(6c) is a linear program, and so, associating dual variables u to the constraint (6b) as shown, and taking the regular LP dual, we get

$$v[\text{LD}] = \text{minimize } \sum_{i=1}^I (c^T x^i) u_i \quad (7a)$$

$$\text{subject to : } Ax^i \geq b, \quad \forall i = 1, \dots, I; \quad (7b)$$

$$\sum_{i=1}^I u_i = 1, \quad (7c)$$

$$u \geq 0. \quad (7d)$$

Recognizing that $\sum_{i=1}^I (c^T x^i) u_i \equiv c^T \left(\sum_{i=1}^I u_i x^i \right)$, and setting $x = \sum_{i=1}^I u_i x^i$, that is x is represented as a nonnegative convex combination of the extreme points of $Cx \geq d, x \geq 0$, we can rewrite Problem (7a)–(7d) as

$$\begin{aligned} v[\text{LD}] &= \text{Minimize} \left\{ c^T x \mid Ax \geq b, Cx \geq d, x \geq 0 \right\} \\ &\equiv v[\text{P}]. \end{aligned}$$

To further understand the mathematical properties of the Lagrangian dual, consider the following proposition that characterizes a saddle point optimum.

Definition 2. A point $(\bar{\pi}, \bar{x})$ with $\bar{\pi} \geq 0$ and $\bar{x}$ feasible to Problem $\text{LR}_{\bar{\pi}}$ is a *saddle point* for $\eta(\pi, x) = c^T x + \pi^T(b - Ax)$ if and only if,

$$\begin{aligned} \max_{\pi \geq 0} \eta(\pi, \bar{x}) &\leq \eta(\bar{\pi}, \bar{x}) \leq \min_{\{x \geq 0 \mid Cx \geq d\}} \eta(\bar{\pi}, x). \end{aligned} \quad (8)$$

Proposition 3. If $\bar{\pi} \geq 0$ and $\bar{x}$ is feasible to Problem $\text{LR}_{\bar{\pi}}$, then $(\bar{\pi}, \bar{x})$ is a saddle point for $\eta(\pi, x) = c^T x + \pi^T(b - Ax)$ if and only if

- (i) $\bar{x}$ is a Lagrangian solution to Problem $\text{LR}_{\bar{\pi}}$ at $\pi = \bar{\pi}$,
- (ii) $A\bar{x} \geq b$,
- (iii) $\bar{\pi}^T(b - A\bar{x}) = 0$.

Proof. Let $(\bar{\pi}, \bar{x})$ satisfy conditions (i)–(iii). Then, by definition of a Lagrangian solution, $\eta(\bar{\pi}, \bar{x}) \leq \min_{\{x \geq 0 \mid Cx \geq d\}} \eta(\bar{\pi}, x)$, which proves the right-hand inequality in Equation (8). Now, from condition (iii), $\eta(\bar{\pi}, \bar{x}) = c^T \bar{x}$, and $A\bar{x} \geq b$, which implies

$$\begin{aligned} \eta(\pi, \bar{x}) &= c^T \bar{x} + \pi^T(b - A\bar{x}) \leq c^T \bar{x} \\ &= \eta(\bar{\pi}, \bar{x}), \quad \forall \pi \geq 0, \end{aligned}$$

thereby proving that $(\bar{\pi}, \bar{x})$ is a saddle point.

Conversely, let $(\bar{\pi}, \bar{x})$ be a saddle point for $\eta(\pi, x) = c^T x + \pi^T(b - Ax)$. Then, by definition, $\eta(\bar{\pi}, \bar{x}) \leq \min_{\{x \geq 0 \mid Cx \geq d\}} \eta(\bar{\pi}, x)$, which proves that $\bar{x}$ is a Lagrangian solution to Problem $\text{LR}_{\bar{\pi}}$ at $\pi = \bar{\pi}$. Moreover,

$\max_{\pi \geq 0} \eta(\pi, \bar{x}) \leq \eta(\bar{\pi}, \bar{x})$, which gives $A\bar{x} \geq b$; else, $\max_{\pi \geq 0} \eta(\pi, \bar{x})$ would be unbounded. Finally, for any row index $j \in \{1, \dots, p\}$, where a_j is the j^{th} row of A , if $(a_j)^T \bar{x} > b_j$, then $\bar{\pi}_j = 0$ because $\bar{\pi}$ is a solution to $\max_{\pi \geq 0} \eta(\pi, \bar{x})$, and condition (iii) is satisfied. Hence proved.

Corollary 1. $v[\text{LD}] = v[\text{LR}_{\pi^*}] = v[\text{LR}_{u^*}]$, where π^* is the vector of optimal Lagrange multipliers obtained by solving Problem LD, and u^* is the (partial) optimal dual vector associated with the complicating constraints obtained by solving Problem P.

Corollary 2. The primal–dual pair (u^*, x_{u^*}) , where x_{u^*} is a Lagrangian solution to Problem LR_{π} at $\pi = u^*$, is a saddle point optimum with $v[\text{LR}_{u^*}] = c^T x_{u^*}$.

Corollary 3. Problems P and LD are essentially LP duals of one another.

Here, we have stated several important corollaries that arise from Theorems 1 and 2, but the proofs are fairly straightforward and have been left as an exercise to the reader. For example, Corollary 1 follows as a direct consequence of Theorem 2 and Proposition 3, used in conjunction with each other. Corollaries 1 and 2 also correlate Lagrangian duality to traditional LP duality theory by proving that the optimal Lagrange multipliers obtained by solving Problem LD are indeed the same as the optimal dual variables associated with the complicating constraints, obtained via regular LP duality. Moreover, all of the results presented above not only prove that solving the Lagrangian dual is optimal to the original linear program, but they also present the necessary *optimality conditions* for the Lagrangian dual, and these optimality conditions are used in designing the algorithms presented in the following section.

Next, to showcase the methodology presented above, consider the following illustrative example:

$$\text{P1: Minimize } z \equiv -x_1 - x_2 \quad (9a)$$

$$\text{subject to: } -x_1 + x_2 \geq -1 \quad : u_1, \quad (9b)$$

$$2x_1 - 3x_2 \geq -6 \quad : v_1, \quad (9c)$$

$$\begin{aligned} -4x_1 - 6x_2 &\geq -18 \quad : v_2, (9d) \\ (x_1, x_2) &\geq 0. \end{aligned} \quad (9e)$$

The optimal solution for Problem P1 is $(x_1^*, x_2^*) = (12/5, 7/5)$, and the corresponding dual vector is $(u_1^*, v_1^*, v_2^*) = (1/5, 0, 1/5)$, with optimum objective function value of $v[\text{P1}] = -19/5$. For the purposes of expositing the Lagrangian approach, we let constraint (9b) serve as the complicating constraint, and dualize this constraint by using the nonnegative scalar $\pi \geq 0$ to obtain the following Lagrangian relaxation of P1:

$$\text{LR}_\pi: \text{Minimize} \{-x_1 - x_2 + \pi(-1 + x_1 - x_2) \mid (9c), (9d), \text{ and } (9e)\}. \quad (10)$$

Rewriting the objective function in Equation (10) as $-\pi + (\pi - 1)x_1 - (\pi + 1)x_2$, and with some algebraic analysis, a complete, explicit characterization of the Lagrangian relaxation function is obtained, given by

$$v[\text{LR}_\pi] = \begin{cases} \frac{7\pi}{2} - \frac{9}{2}, & 0 \leq \pi \leq \frac{1}{5} \\ -\frac{11\pi}{4} - \frac{13}{4}, & \frac{1}{5} \leq \pi \leq 5 \\ -3\pi - 2, & \pi \geq 5 \end{cases}. \quad (11)$$

Figure 1 displays $v[\text{LR}_\pi]$ as a function of π (for brevity, shown only for $0 \leq \pi \leq 1$), and the corresponding Lagrangian dual problem is LD: Maximize $\{(11) \mid \pi \geq 0\}$. As seen in the figure, the maximum of this Lagrangian relaxation function and, consequently, the optimum for Problem LD (and Problem P1)

occurs at $\pi^* = 1/5$, with the optimum objective function value of $v[\text{LD}] \equiv v[\text{P1}] = -19/5$. Also, note that the optimal value of the Lagrange multiplier obtained here is indeed the same as the optimal value of the dual variable associated with the complicating constraint (9b); that is, $\pi^* \equiv u_1^* = 1/5$. However, the optimal values of the dual variables corresponding to the remaining constraints as well as the primal solution cannot be obtained via the solution of the Lagrangian dual problem in this case.

So, how can the primal solution vector be recovered from the solution to the Lagrangian dual problem? In order to obtain the optimal values of the decision variables in the space of the original problem, we use the mathematical characterization of a Lagrangian solution provided in Theorem 1 in concert with primal feasibility conditions. From Theorem 1, we know that

$$\pi^*(-1 + x_1 - x_2) = 0 \Rightarrow x_1 = 1 + x_2. \quad (12)$$

Moreover, using Equation (12) along with primal feasibility of constraints (9c) and (9d) yields

$$\left. \begin{aligned} 2x_1 - 3x_2 &\geq -6 \Rightarrow x_2 \leq 8 \\ -4x_1 - 6x_2 &\geq -18 \Rightarrow x_2 \leq 7/5 \end{aligned} \right\} \Rightarrow x_2 \leq 7/5. \quad (13)$$

The objective function of P1 is $z = -x_1 - x_2 \equiv -1 - 2x_2$, and hence, utilizing the primal feasibility bound for x_2 from Equation (13),

Figure 1. Optimal value of the Lagrangian relaxation problem as a function of the Lagrange multiplier.

we get that the optimal (minimum) objective function value occurs at $x_2^* = 7/5$, and correspondingly, $x_1^* = 1 + x_2^* = 12/5$, which is indeed the primal optimal solution. Also, notice that as the bound $x_2^* = 7/5$ is obtained from Equation (9d), this constraint is tight at optimality.

Remark 3. As seen in Fig. 1, the Lagrangian relaxation function for a minimization problem is a *continuous, piecewise-linear, concave function* (for details, refer to the section titled “Solution Methodologies For The Lagrangian Dual”). Indeed, each of the linear functions in this piecewise-linear concave function can be shown to correspond to an *extreme point* of the feasible region of Problem LR_π ; that is, extreme points of $\{Cx \geq d, x \geq 0\}$. (Alternatively, one can say that each extreme point of the feasible region of LR_π *generates* a unique linear function.) In the example above, the extreme points of Equation (10) are given by $\{(0, 0), (9/2, 0), (3/4, 5/2), (0, 2)\}$, and, for example, the linear function $v[LR_\pi] = \frac{7\pi}{2} - \frac{9}{2}$ corresponds to the extreme point $(9/2, 0)$, that is, for values of $0 \leq \pi \leq 1/5$, the optimum to Problem LR_π occurs at this extreme point. Similarly, the other two linear functions in Equation (10) can be shown to correspond to the extreme points $(3/4, 5/2)$ and $(0, 2)$, respectively. Moreover, based on continuity of the Lagrangian relaxation function, at the optimum value of $\pi^* = 1/5$, the Lagrangian solutions $(9/2, 0)$ and $(3/4, 5/2)$ are both optimal to Problem LR_π . Furthermore, the extreme point $(0, 0)$ is not an optimal solution of Problem LR_π for any value of $\pi \geq 0$, and is therefore not associated with any linear function.

Remark 3 brings to the fore a very important aspect of this Lagrangian approach. As the Lagrangian relaxation function is a continuous, piecewise-linear, concave function, the Lagrangian dual problem which maximizes this function is a “nondifferentiable” optimization problem, and so, the solution to this problem cannot be achieved via classical optimization methods, which mostly rely on differentiability of functions for computing gradients and Hessian matrices. Hence,

a new set of optimization algorithms need to be employed for solving this challenging class of problems.

SOLUTION METHODOLOGIES FOR THE LAGRANGIAN DUAL

Optimization problems having convex, but nondifferentiable objective functions are called *nondifferentiable optimization* (NDO) problems [8]. Within large-scale optimization frameworks, such NDO problems arise in algorithms that cater toward solving min–max problems, dynamic programming, piecewise approximations, and stochastic optimization. One of the important application areas for NDO problems is in Lagrangian duality, and the most prominently featured NDO-based solution methodology for solving the Lagrangian dual problem is the *subgradient optimization* algorithm [8,9]. Other methods that are also commonly used are cutting planes [10], column generation [11,12], and of more recent flavor are bundle methods [13] and volume algorithms [14–16].

Here, we begin by considering the basic version of a subgradient optimization approach for solving Problem LD. To motivate this discussion, note that $v[LR_\pi]$ is an *implicit* function of π , and as seen in the proof of Theorem 2,

$$\begin{aligned} v[LR_\pi] &= \text{minimize } \left\{ c^T x + \pi^T (b - Ax) \right. \\ &\quad \left. | Cx \geq d, x \geq 0 \right\} \\ &= \text{minimize } \left\{ c^T x^i + \pi^T (b - Ax^i) \right\}, \\ &\quad i=1, \dots, p \end{aligned} \tag{14}$$

and so, $v[LR_\pi]$ is the *lower envelope* of a family of affine functions, and is therefore a *concave function* of π . The points where the function is not differentiable are called *breakpoints*, and at these points, the optimal solution of Problem LR_π is not unique. (In the example presented in the section titled “Properties of the Lagrangian Dual”, breakpoints occur at $\pi = 1/5$ and 5 , and at these points, $v[LR_\pi]$ is not only nondifferentiable but also has multiple optimal solutions. At $\pi = 1/5$,

both extreme points (9/2,0) and (3/4,5/2), as well as all points belonging to the facet (9c) are optimal to Problem LR_π).

A piecewise-linear concave function is differentiable almost everywhere except over the set of breakpoints and at these points, as no gradient information is available, *subgradients* prove to be a very useful substitute.

Definition 3. If $f(x) : \mathbb{R}^n \rightarrow \mathbb{R}$ is a concave function, then for any $x^0 \in \mathbb{R}^n$, $\gamma(x^0)$ is a *subgradient* of $f(x)$ at x^0 if and only if

$$f(x) \leq f(x^0) + \left(\gamma(x^0) \right)^T (x - x^0), \quad \forall x \in \mathbb{R}^n.$$

Definition 4. The set of all subgradients at a point $x^0 \in \mathbb{R}^n$ is called the *subdifferential* of $f(x)$ at x^0 , and is denoted as $\partial f(x^0)$.

Proposition 4. If $\bar{\pi} \geq 0$ is a Lagrange multiplier with corresponding Lagrangian solution $x_{\bar{\pi}}$, then $\gamma \equiv (b - Ax_{\bar{\pi}})$ is a subgradient of $v[LR_{\pi}]$ at $\bar{\pi}$.

Subgradient Algorithm

- Step 1:** Set iteration counter $k = 0$, choose initial Lagrange multipliers π^k , and let η^* be the current guess for the optimal value of Problem LD. Go to Step 2.
- Step 2:** Solve Problem LR_π with $\pi = \pi^k$, to obtain the Lagrangian solution x_{π}^k , with objective function value $\eta_k = v[LR_{\pi^k}]$. Go to Step 3.
- Step 3:** Compute the subgradient of $v[LR_{\pi}]$ at x_{π}^k as $\gamma^k = (b - Ax_{\pi}^k)$. Go to Step 4.
- Step 4:** Let $\pi^{k+1} = \max\{0, \pi^k + \mu_k \gamma^k\}$, where $\mu_k = \frac{\eta^* - \eta_k}{\|\gamma^k\|^2}$ is the *step length* in the direction of the subgradient. If $\|\pi^{k+1} - \pi^k\| \leq \varepsilon$, for some optimality tolerance $\varepsilon > 0$, stop; return π^k as the optimal solution to Problem LD with objective function value $v[LR_{\pi^k}]$. Else, go to Step 5.
- Step 5:** Set $k = k + 1$, and go to Step 2.

Remark 4. In computing the step lengths, the subgradient algorithm uses the unknown optimal value η^* (or *target value*, which lends its name to “target value methods” [15,17]), and a common stumbling block with practical implementations of subgradient algorithms is to overestimate the value of η^* . If the objective function value fails to change for many iterations, then it is likely that η^* has been overestimated, and the corresponding step

Proof. For notational ease, let $\eta_{\pi} = v[LR_{\pi}]$. As $x_{\bar{\pi}}$ is a Lagrangian solution, from Definition 2,

$$\begin{aligned} \eta_{\pi} &\leq c^T x_{\bar{\pi}} + \pi^T (b - Ax_{\bar{\pi}}) \\ &= c^T x_{\bar{\pi}} + \bar{\pi}^T (b - Ax_{\bar{\pi}}) + (\pi - \bar{\pi})^T (b - Ax_{\bar{\pi}}) \\ &= \eta_{\bar{\pi}} + (\pi - \bar{\pi})^T (b - Ax_{\bar{\pi}}). \end{aligned}$$

Setting $\gamma \equiv (b - Ax_{\bar{\pi}})$ completes the proof.

Now, let π^* be the (unknown) optimal Lagrange multipliers with $\eta^* = v[LR_{\pi^*}]$. The subgradient optimization algorithm is an *iterative procedure*, where, at some iteration k , given the current values of the Lagrange multipliers π^k , a step is taken in the direction of the subgradient $\gamma^k = (b - Ax_{\pi}^k)$, using an appropriately determined step length, to determine new values of the multipliers and the process continues until convergence is achieved.

A formal statement of the subgradient algorithm for solving the Lagrangian dual problem is given below.

lengths are too large. Hence, as a “corrector” mechanism, a modified step length is used, given by

$$\pi^{k+1} = \max \left\{ 0, \pi^k + \frac{\xi(\eta^* - \eta_k)}{\|\gamma^k\|^2} \gamma^k \right\}, \quad (15)$$

where, $\xi \in (0, 2)$, and this scalar is reduced whenever there is no improvement for a significant number of iterations.

Figure 2. Convergence of the subgradient algorithm as a function of the number of iterations for solving Problem P1.

Given the dual multipliers in Equation (15), it can be shown that the sequence of iterates $\|\pi^k - \pi^*\|$ is monotone nonincreasing and therefore the algorithm produces a convergent sequence of dual multipliers. However, an important theoretical consideration is to determine the values of the step lengths, μ_k , such that not only the dual multipliers converge but also the objective function value converges to the *optimal* solution with a reasonable rate of convergence. A fundamental result in Ref. 9 states that the sequence of iterates $\{\eta_k\}$ converges to η^* if and only if $\{\mu_k\} \rightarrow 0$ and $\sum_{i=0}^{\infty} \mu_k \rightarrow \infty$. The condition $\{\mu_k\} \rightarrow 0$ is necessary to ensure that the step lengths do not continually “overshoot” the optimum, while $\sum_{i=0}^{\infty} \mu_k \rightarrow \infty$ guarantees that the step lengths are large enough to get to π^* from the original estimate of π^0 . As is evident from the foregoing discussion, getting a subgradient algorithm to work in practice requires tweaking the parameters repeatedly to ensure convergence and to make matters more complicated, these parameters are often problem-specific as well. For a detailed proof of convergence, see Refs 9 and 18.

The subgradient algorithm described above was implemented in MATLAB on a computer running Windows XP with

an Intel Core 2 Duo, 2 GHz, 2 MB RAM processor. As seen in the results, beginning with $\pi^0 = 0$, and an initial estimate of the optimum $\eta^* = -5$, the algorithm converged to an ε -optimum in 77 iterations, in 0.594 CPU seconds, with an optimality tolerance of $\varepsilon = 0.0005$. Figure 2 plots the objective function value produced by the subgradient algorithm at iteration k , and as clearly seen in the figure, in the initial stages, the algorithm moves rapidly toward the optimum, and subsequently follows a zigzag pattern before achieving the required tolerance level for convergence. Table 1 records several parameters related to the performance of the subgradient algorithm, applied to Problem P1, for a few select iterations. Notice that the values of the step lengths converge to zero, thereby satisfying the convergence criterion, and the value of the dual multiplier converges to $\pi^* = 1/5$. Also, note that the values of (x_1^k, x_2^k) displayed in the table are the optimal values for the Lagrangian relaxation problem (in the space of the “easy constraints”), and are not optimal to the original primal problem.

The subgradient algorithm outlined above works only in the dual space of the Lagrangian dual problem, and therefore the

primal solution to Problem P is not recovered by this algorithm. Moreover, as seen in Fig. 2, taking step lengths along the subgradient direction also results in a zigzagging phenomenon that causes the algorithm to slowly crawl toward the optimum. To tackle these shortcomings, a more refined class of subgradient algorithms, namely *primal-dual subgradient algorithms*, has been developed for solving NDO problems. In such methods, a sequence of primal and dual iterates is generated by employing a Lagrangian dual function and a penalty function that satisfies some properties. Consequently, such methods admit both primal and dual optimal solutions, and convergence follows based on narrowing the gap between the penalty function and the Lagrangian dual.

For more details on such primal-dual subgradient methods as well more advanced *conjugate gradient* schemes (that allow for modified gradient directions and improved convergence properties), we refer the reader to Refs 19 and 20. Apart from gradient-based schemes, many other approaches have also been developed for solving the Lagrangian dual problem; for details, see Ref. 7.

EXTENSIONS AND CONCLUSIONS

As discussed earlier (see Remark 3), recognizing that each of the extreme points of the feasible region of LR_π generates a unique linear function, the linkage between the Lagrangian approach and other well-known large-scale LP methods, namely Dantzig-Wolfe decomposition [11,12] and

Benders' decomposition [21] can be further analyzed. Indeed, the astute reader would have already encountered many of the standard elements of decomposition methods in this article, particularly in the proofs of Theorem 2 and Proposition 3, as well as in the subsequent discussion related to continuous, piecewise-linear, concave functions. However, the other articles of this encyclopedia showcase decomposition techniques (see **Dantzig-Wolfe Decomposition** and **Benders Decomposition**) and in the following chapter a detailed discussion relating the Lagrangian dual to these decomposition methods is presented (see **Relationship Among Benders, Dantzig-Wolfe, and Lagrangian Optimization**). Hence, for the remainder of this article, we will proceed in a different direction and focus on a very brief extension of the Lagrangian dual approach geared toward discrete optimization problems.

In so far, while we have focused on using the Lagrangian dual approach for solving LP problems, many of these results and discussions can be extended to the IP case. Indeed, the true strength of the Lagrangian dual approach is realized when solving problems with discrete variables as the bounds provided by the Lagrangian dual are often much tighter than the bounds obtained from the basic LP relaxation. Consequently, there has been extensive research geared toward applying Lagrangian dual schemes to IP problems [1,5-7,22,23].

Now, suppose that in the primal problem, the decision variables are restricted to be integer, that is, IP: Minimize

$\{c^T x | Ax \geq b, Cx \geq d, x \in \mathbb{Z}_+^n\}$. Denoting $\Omega \equiv \{Cx \geq d, x \in \mathbb{Z}_+^n\}$, the Lagrangian relaxation problem for IP relative to the constraints $Ax \geq b$ and a conformable vector $\pi \geq 0$ is given by LR_π : Minimize $\{c^T x + \pi^T(b - Ax) | x \in \Omega\}$, and the corresponding Lagrangian dual problem is LD: Maximize $\{LR_\pi | \pi \geq 0\}$. Akin to the development in the LP case, there are several mathematical properties of the Lagrangian dual formulation that can be proven for the IP case, but the most fundamental result is that the objective function value of the Lagrangian dual is at least as tight as the one obtained from the standard LP relaxation, and furthermore, if the constraint set $\Omega \equiv \{Cx \geq d, x \in \mathbb{Z}_+^n\}$ satisfies the so-called *integrality property*, then the Lagrangian dual produces a bound that is the same as the LP relaxation bound. These two properties are summarized in the theorems below; for proofs, see Refs 1,4,5,7, and 23.

Theorem 3. $v[LP] \leq v[LD] \leq v[IP]$, where LP is the linear programming relaxation of IP.

Theorem 4. If the Lagrangian relaxation problem, LR_π , satisfies the integrality property, that is, $\text{conv}(\Omega) \equiv \{Cx \geq d, x \geq 0\}$, then $v[LP] \equiv v[LD] \leq v[IP]$, where $\text{conv}(\cdot)$ represents the convex hull of the constraints $(\cdot)$.

To gauge the performance of the Lagrangian dual formulation in the case of

integer programs, suppose that we impose integer restrictions on the x variables in Problem P1. In this case, the optimum occurs at $(x_1^*, x_2^*) = (2, 1)$, with optimal objective function value of $v[P1] = -3$. However, solving the Lagrangian dual yields $\pi^* = 1/3$ with optimal objective function value of $v[LD] = -11/3$, with the corresponding primal solution $(x_1^*, x_2^*) = (3, 1)$. The solid and dashed lines in Fig. 3 indicate the performance of the Lagrangian relaxation function of IP and its LP relaxation, respectively, for different values of $\pi \geq 0$ (as before, displayed only for $0 \leq \pi \leq 1$). In this case, as the conditions of Theorem 4 are not satisfied; that is, integrality property does not hold, the Lagrangian dual function yields a tighter bound than the standard LP relaxation. The “duality gap” in this case is $v[P1] - v[LD] = 2/3$. Notice that the duality gap between IP and its corresponding LP relaxation is $v[P1] - v[LP] = 4/5$; hence, the Lagrangian dual formulation provides a tighter bound as compared to the LP relaxation, and this fact can be further verified from Fig. 3.

In this article, we developed the basic methodology for solving large-scale LP problems via a Lagrangian dual approach. Beginning with a formulation of the Lagrangian dual problem, we proved that the optimal objective function value obtained by solving the Lagrangian dual is optimal to the original linear program, and moreover, theorems and propositions that characterized the mathematical properties of the

Figure 3. Optimal value of the Lagrangian relaxation for IP as a function of the Lagrange multiplier.

Lagrangian dual to relate this approach to classical LP duality were also included. Recognizing that the Lagrangian dual formulation is a NDO problem, a subgradient algorithm was prescribed for solving this problem, and computational results for an illustrative example were presented. A brief extension of this approach for solving integer programs can also be found in this article.

Alongside a methodological framework, there are several other questions related to the Lagrangian approach that also need to be addressed, primarily the ones arising from a *modeling perspective*. For example, questions such as—what constraints should be dualized in a Lagrangian scheme; does the original problem formulation affect the strength of the Lagrangian dual problem bound; can the Lagrangian relaxation bounds be tightened by incorporating cutting planes—are critical to the success of the Lagrangian optimization approach and need to be answered *prior* to setting up the Lagrangian dual and selecting an appropriate algorithm. For such perspectives, we refer the reader to Ref. 7. In conclusion, the Lagrangian dual approach, when applied judiciously by selecting the appropriate complicating constraints along with a convergent algorithm, can prove to be a very useful tool for solving large-scale linear and IP problems.

As an aside, note that the term *Lagrangian* has also been often used in the optimization literature. An internet search for the terms Lagrangian dual and Lagrangean dual yielded a comparable number of references, and therefore we conclude that both terms have been used interchangeably by the optimization community and represent the same idea presented in this article.

LAGRANGIAN OPTIMIZATION METHODS FOR NONLINEAR PROGRAMMING

ANGELIA NEDIĆ

Department of Industrial and Enterprise
Systems Engineering, University of Illinois
at Urbana-Champaign, Urbana, Illinois

LAGRANGIAN RELAXATION AND ITS DUALITY THEORY

In a classical constrained optimization, an objective function has to be minimized (or maximized) in the presence of finitely many constraints. Some of the constraints may pose difficulties for solving the problem efficiently, while the removal of these “difficult” constraints results in an optimization problem that can be solved efficiently.

Lagrangian relaxation is one of the basic tools for dealing with difficult constraints in nonlinear constrained optimization problems. Lagrangian relaxation is a technique that “relaxes” the difficult constraints by penalizing (pricing) the constraints and bringing them into the objective. This gives rise to an alternative constrained problem, known as the *dual of the original problem*. While the dual problem bears strong relations with the original problem, it is not necessarily equivalent to the original problem. The duality theory, also known as *Lagrangian duality*, provides conditions under which the dual and the original problem are equivalent.

Lagrangian relaxation and its duality theory have been widely used for the design and analysis of optimization problems arising in vast range of engineering and other applied sciences. Aside from enabling us with framework for dealing with “difficult” constraints, Lagrangian relaxation often provides us with suitable decomposition schemes. Such schemes have been particularly useful when dealing with problems of large size (large

number of variables and/or constraints). More recently, with the advances in wired and wireless communication technology, Lagrangian relaxation is used in the design of algorithms for performance optimization of large systems with distributed information such as sensor networks, Internet, and other communication systems [1–3].

Primal Problem and Its Dual

The power of Lagrangian relaxation lies within constrained optimization problems. A general constrained optimization problem has the following form:

$$\begin{aligned} &\text{minimize} && f(x) \\ &\text{subject to} && g_j(x) \leq 0 \quad j = 1, \dots, m, \\ & && h_i(x) = 0 \quad i = 1, \dots, r, \\ & && x \in X, \end{aligned} \quad (1)$$

where $f: \mathbb{R}^n \rightarrow \mathbb{R}$, $g_j: \mathbb{R}^n \rightarrow \mathbb{R}$ for all j , $h_i: \mathbb{R}^n \rightarrow \mathbb{R}$ for all i , and $X \subseteq \mathbb{R}^n$. In general, the functions f , g_j , and h_i need not be defined on the entire $\mathbb{R}^n$, in which case extended-real value functions are considered [4]. To keep the exposition simple, we will not deal with the extended-real value functions.

The problem in Equation (1) is referred to as *primal problem* and its optimal value is denoted by f^* , that is,

$$f^* = \inf_{\substack{g_j(x) \leq 0, j=1, \dots, m \\ h_i(x) = 0, i=1, \dots, r, x \in X}} f(x).$$

A vector x is said to be *primal feasible* if it is feasible for the primal problem, i.e., $g_j(x) \leq 0$ for all j , $h_i(x) = 0$ for all i and $x \in X$. Often, for a more compact notation, the vector functions $g(x)$ and $h(x)$ are defined, respectively, as $g(x) = (g_1(x), \dots, g_m(x))^T$ and $h(x) = (h_1(x), \dots, h_r(x))^T$ for $x \in \mathbb{R}^n$. Throughout the rest of the discussion, for a vector u , the notation $u \leq 0$ (or $u < 0$) denotes the component-wise inequalities, that is, $u_i \leq 0$ (or $u_i < 0$) for all coordinate indices i . Thus, the relations $g(x) \leq 0$ and $h(x) = 0$ in vector notation correspond, respectively, to $g_j(x) \leq 0$ for all j and $h_i(x) = 0$ for all i .

The basic underlying idea of the Lagrangian relaxation is to associate another problem with primal problem (1) and establish the conditions for the equivalence of the two problems. The problem associated with the primal is obtained by penalizing the constraints $g_j(x) \leq 0$ and $h_i(x) = 0$ and bringing them into the objective of the new problem. This is done by assigning a nonnegative scalar μ_j to each inequality constraint $g_j(x) \leq 0$, and assigning a scalar λ_i (unrestricted in sign) to each constraint $h_i(x) = 0$. Then, the functions $\sum_{j=1}^m \mu_j g_j(x)$ and $\sum_{i=1}^r \lambda_i h_i(x)$ are formed, and the objective for the new problem is defined using $f(x) + \sum_{j=1}^m \mu_j g_j(x) + \sum_{i=1}^r \lambda_i h_i(x)$. The problem associated with Equation (1) is given by

$$\begin{aligned} \text{maximize } q(\mu, \lambda) &\triangleq \inf_{x \in X} \left(f(x) + \sum_{j=1}^m \mu_j g_j(x) \right. \\ &\quad \left. + \sum_{i=1}^r \lambda_i (a_i^T x - b_i) \right) \\ \text{subject to } &\mu \geq 0, \quad \mu \in \mathbb{R}^m \\ &\lambda \in \mathbb{R}^r, \end{aligned} \quad (2)$$

where μ and λ are the vectors with components μ_j and λ_i , respectively. This problem is referred to as the *dual problem* associated with the primal problem in Equation (1). Its optimal value is denoted by q^* , that is,

$$q^* = \sup_{\substack{\mu \geq 0, \mu \in \mathbb{R}^m \\ \lambda \in \mathbb{R}^r}} q(\mu, \lambda).$$

Within the Lagrangian relaxation literature, the dual variables μ and λ are known as *Lagrangian multipliers* or *multipliers*. A pair (μ, λ) is said to be *dual feasible* if $\mu \geq 0$. The dual function $q(\mu, \lambda)$ is always *concave*, regardless of the structure of the primal problem (i.e., even when problem (1) is nonconvex, discontinuous, discrete, etc.) [4,5]. While the dual function $q(\mu, \lambda)$ is always concave in $(\mu, \lambda) \in \mathbb{R}^m \times \mathbb{R}^r$, its domain is not necessarily the whole space $(\mu, \lambda) \in \mathbb{R}^m \times \mathbb{R}^r$ [4,5]. Nevertheless, the dual problem is always a concave maximization problem with simple explicit constraints.

The difficulty in solving the dual problem lies in the “implicit” form of the dual function. Specifically, note that the evaluation of the dual function requires one to solve a constrained convex minimization problem entries b_i .

$$q(\mu, \lambda) = \inf_{x \in X} (f(x) + \mu^T g(x) + \lambda^T h(x)). \quad (3)$$

This problem is referred to as *Lagrangian subproblem*. From this perspective, the use of Lagrangian relaxation is the most successful when the solution to Lagrangian subproblem, $\inf_{x \in X} (f(x) + \mu^T g(x) + \lambda^T h(x))$, is available in a closed form or a good approximation can be computed efficiently.

Luckily, arising in various applications, there are many problems for which a closed form solution to Lagrangian subproblem exists [6]. For such problems, the dual problem is often easier to solve than the primal problem. However, to have the guarantee that solving the dual is equivalent to solving the primal, we have to ensure that certain duality relations are in place. These relations are discussed in the following section.

Weak and Strong Duality

At the heart of the duality lies a relation providing a fundamental connection between the optimal values of primal problem (1) and its associated dual problem (2). This relation states that the dual function value $q(\mu, \lambda)$ provides a lower bound for the primal optimal value f^* , that is,

$$q(\mu, \lambda) \leq f^* \quad \text{for all } \mu \in \mathbb{R}^m, \mu \geq 0 \text{ and } \lambda \in \mathbb{R}^r. \quad (4)$$

This relation is often referred to as *lower bounding property* [6]. The relation is implied by the inclusion $\{x \in X \mid g(x) \leq 0, h(x) = 0\} \subseteq X$, as follows:

$$\begin{aligned} q(\mu, \lambda) &= \inf_{x \in X} (f(x) + \mu^T g(x) + \lambda^T h(x)) \\ &\leq \inf_{\substack{x \in X \\ g(x) \leq 0, h(x) = 0}} (f(x) + \mu^T g(x) + \lambda^T h(x)). \end{aligned}$$

Noting that $\mu^T g(x) \leq 0$ and $\lambda^T h(x) = 0$ for any $\mu \geq 0$ and for any $x \in X$ such that $g(x) \leq 0$

and $h(x) = 0$, we have

$$q(\mu, \lambda) \leq \inf_{\substack{x \in X \\ g(x) \leq 0, h(x) = 0}} f(x) = f^*.$$

This bounding property of dual function value $q(\mu, \lambda)$ has been extensively used in the algorithms for integer and mixed integer programming, such as branch-and-bound [4].

The lower bounding property is the key relation that leads to the duality results, known as *weak and strong duality*. Weak duality states that the dual optimal value q^* is never greater than the primal optimal value f^* .

Theorem 1. *Weak duality always holds, that is,*

$$q^* \leq f^*.$$

The result is a direct consequence of the lower bounding property in Equation (4), from which it follows by taking the supremum over all $\mu \in \mathbb{R}^m$ with $\mu \geq 0$ and all $\lambda \in \mathbb{R}^r$. The power of the weak duality relation is in its generality: no assumptions on the structure of the primal problem are needed.

A particularly important case of the weak duality is the case when the primal and the dual optimal values are equal: $q^* = f^*$. This relation is known as the *strong duality* relation, which provides a ground for the equivalence between the primal problem and its dual.

The strong duality does not hold in general. Most of the known strong duality results reside within *convex* constrained optimization problems. A convex constrained optimization problem is a special case of the problem in Equation (1), defined as follows:

Definition 1. The problem in Equation (1) is convex if

- (a) the objective function $f: \mathbb{R}^n \rightarrow \mathbb{R}$ is convex;
- (b) each function $g_j: \mathbb{R}^n \rightarrow \mathbb{R}$ is convex;
- (c) each function $h_i: \mathbb{R}^n \rightarrow \mathbb{R}$ is affine, that is, for each i , we have $h_i(x) = a_i^T x - b_i$ with $a_i \in \mathbb{R}^n$ and $b_i \in \mathbb{R}$;
- (d) the set $X \subseteq \mathbb{R}^n$ is closed and convex.

In general, the functions f and g_j need not be convex on the entire $\mathbb{R}^n$, but rather be closed and convex in extended-real value sense [5,7,8].

Strong duality does not hold for any convex problem. In particular, in order to have $q^* = f^*$ for a convex primal problem, some additional conditions are needed. Such conditions are often referred to as *constraint qualifications* [4,5]. The two most widely used conditions are *Slater condition* and *linear constraints*. Slater condition requires that a point $\bar{x} \in X$ exists such that $g_j(\bar{x}) < 0$ for all $j = 1, \dots, m$. Linear condition [4,5,7] basically requires that $X = \mathbb{R}^n$ and all inequality constraints $g_j(x) \leq 0$ are “affine,” that is, $g_j(x) = c_j^T x - d_j$ with a vector $c_j \in \mathbb{R}^n$ and a scalar d_j for each j . Other conditions exist that are reliant on the recession cones of closed convex sets [5,7,9]. The Slater and linear constraint qualifications actually guarantee more than the strong duality relation. These conditions also guarantee the existence of an optimal dual solution, that is, the existence of a multiplier pair (μ^*, λ^*) with $\mu^* \geq 0$ and such that $q(\mu^*, \lambda^*) = q^*$.

Under the Slater condition, we have the following strong duality result.

Theorem 2 [Slater; 5]. *Let the primal problem be convex and let its optimal value f^* be finite, that is, $f^* > -\infty$. Assume also that the Slater condition holds. Then, we have the following:*

- (a) *there is no duality gap, that is, $q^* = f^*$;*
- (b) *the set of dual optimal solutions is nonempty and bounded.*

The results of Theorem 2 hold, except for the boundedness of the optimal dual set, when the Slater condition is replaced with the linear constraint qualification [4,5].

Lagrangian Saddle Point and KKT conditions

Given a primal problem (1), its Lagrangian function is the function involved in the definition of the dual problem, that is, its Lagrangian function is

$$\mathcal{L}(x, \mu, \lambda) = f(x) + \mu^T g(x) + \lambda^T h(x) \quad \text{for} \\ x \in X, \mu \in \mathbb{R}_+^m, \text{ and } \lambda \in \mathbb{R}^r,$$

where $\mathbb{R}_+^m$ is the nonnegative orthant in $\mathbb{R}^m$. Thus, we have

$$q^* = \sup_{\mu \in \mathbb{R}_+^m, \lambda \in \mathbb{R}^r} \inf_{x \in X} \mathcal{L}(x, \mu, \lambda). \quad (5)$$

Furthermore, we have for any $x \in \mathbb{R}^n$,

$$\sup_{\mu \in \mathbb{R}_+^m, \lambda \in \mathbb{R}^r} \mathcal{L}(x, \mu, \lambda) = \begin{cases} f(x) & \text{if } g(x) \leq 0 \text{ and} \\ & h(x) = 0, \\ +\infty & \text{otherwise.} \end{cases}$$

Thus, it follows

$$\inf_{x \in X} \sup_{\mu \in \mathbb{R}_+^m, \lambda \in \mathbb{R}^r} \mathcal{L}(x, \mu, \lambda) = \inf_{\substack{x \in X \\ g(x) \leq 0, h(x) = 0}} f(x) = f^*.$$

From the preceding relation and the relation in Equation (5), we see that the weak duality is equivalent to the following inequality for the Lagrangian function:

$$\begin{aligned} & \sup_{\mu \in \mathbb{R}_+^m, \lambda \in \mathbb{R}^r} \inf_{x \in X} \mathcal{L}(x, \mu, \lambda) \\ & \leq \inf_{x \in X} \sup_{\mu \in \mathbb{R}_+^m, \lambda \in \mathbb{R}^r} \mathcal{L}(x, \mu, \lambda). \end{aligned}$$

The strong duality corresponds to the case when the preceding inequality holds with equality, that is,

$$\begin{aligned} & \sup_{\mu \in \mathbb{R}_+^m, \lambda \in \mathbb{R}^r} \inf_{x \in X} \mathcal{L}(x, \mu, \lambda) \\ & = \inf_{x \in X} \sup_{\mu \in \mathbb{R}_+^m, \lambda \in \mathbb{R}^r} \mathcal{L}(x, \mu, \lambda). \end{aligned}$$

There is a deeper relation between strong duality conditions, and primal and dual optimal solutions of a convex primal problem. To describe this, we need the notion of a saddle point.

Definition 2. A tuple (x^*, μ^*, λ^*) such that $x^* \in X$ and $\mu^* \geq 0$ is a *saddle point of the Lagrangian function* if the following relation holds:

$$\mathcal{L}(x^*, \mu, \lambda) \leq \mathcal{L}(x^*, \mu^*, \lambda^*) \leq \mathcal{L}(x, \mu^*, \lambda^*)$$

for all $x \in X$, $\mu \in \mathbb{R}_+^m$, and $\lambda \in \mathbb{R}^r$.

In other words, (x^*, μ^*, λ^*) is a saddle point of $\mathcal{L}(x, \mu, \lambda)$ if

$$\begin{aligned} & \max_{\mu \in \mathbb{R}_+^m, \lambda \in \mathbb{R}^r} \mathcal{L}(x^*, \mu, \lambda) = \mathcal{L}(x^*, \mu^*, \lambda^*) \\ & = \min_{x \in X} \mathcal{L}(x, \mu^*, \lambda^*) \end{aligned} \quad (6)$$

Note that Lagrangian function is linear in (μ, λ) for every x fixed and, therefore, concave in (μ, λ) . In view of this, the first equality in relation (6) states that (μ^*, λ^*) is a maximizer of the concave function $(\mu, \lambda) \mapsto \mathcal{L}(x^*, \mu, \lambda)$ over the set $\mathbb{R}_+^m \times \mathbb{R}^r$. When the primal problem is convex, its Lagrangian function is convex in x for every fixed $(\mu, \lambda) \in \mathbb{R}_+^m \times \mathbb{R}^r$. Thus, in the convex case, the second equality in relation (6) states that $x^* \in X$ is a minimizer of the convex function $x \mapsto \mathcal{L}(x, \mu^*, \lambda^*)$ over the set X .

The primal/dual optimal solutions of a convex minimization problem can be characterized as follows.

Theorem 3 [Lagrangian Saddle Point; 4,5]. *Let the primal problem be convex. Then, a vector $x^* \in X^*$ is primal optimal and a multiplier pair $(\mu^*, \lambda^*) \in \mathbb{R}_+^m \times \mathbb{R}^r$ is dual optimal if and only if (x^*, μ^*, λ^*) is a saddle point of the Lagrangian function.*

By using the first-order optimality conditions for the “max” problem in relation (6), Theorem (3) can be stated in an equivalent form.

Theorem 4 [4,5]. *Let the primal problem be convex. Then, a vector $x^* \in X^*$ is primal optimal and a multiplier pair $(\mu^*, \lambda^*) \in \mathbb{R}_+^m \times \mathbb{R}^r$ is dual optimal if and only if*

- (a) x^* is primal feasible, that is, $x^* \in X$, $g(x^*) \leq 0$, and $Ax = b$;
- (b) (μ^*, λ^*) is dual feasible, that is, $\mu^* \geq 0$;
- (c) $\mathcal{L}(x^*, \mu^*, \lambda^*) = \min_{x \in X} \mathcal{L}(x, \mu^*, \lambda^*)$;
- (d) complementary slackness holds, that is, $(\mu^*)^T g(x^*) = 0$.

Since we assume that the primal problem is convex, we have $h(x) = Ax - b$, where A is

an $r \times n$ matrix and $b \in \mathbb{R}^r$. When the objective function f and the constraint functions g_j are differentiable, and $X = \mathbb{R}^n$, the condition (c) of Theorem 4 can be equivalently stated as

$$\nabla f(x^*) + \sum_{j=1}^m \mu_j^* \nabla g_j(x^*) + A^T \lambda^* = 0.$$

In this case, Theorem 4 provides necessary and sufficient conditions for primal–dual optimality of tuple (x^*, μ^*, λ^*) . These conditions are commonly known as *Karush–Kuhn–Tucker conditions* (KKT).

ALGORITHMS

The algorithms we discuss here are exclusively for convex (primal) problems. Roughly speaking, there are two types of problems that we often like to solve when dealing with Lagrangian relaxation. One is the problem of determining the saddle points of the Lagrangian function, thus finding both primal and dual optimal solutions. The other problem is the dual problem itself, when we want to determine a dual optimal solution or just the dual optimal value.

Algorithms for Saddle Point Problems

Instead of focusing only on the saddle point of Lagrangian, we consider a generic saddle point problem of a convex–concave function. A generic saddle point problem consists of determining a pair $(x^*, y^*) \in X \times Y$ such that

$$L(x^*, y) \leq L(x^*, y^*) \leq L(x, y^*) \quad \text{for all} \\ x \in X \text{ and } y \in Y,$$

where X and Y are closed convex sets in $\mathbb{R}^n$ and $\mathbb{R}^m$, respectively, and $L(x, y) : \mathbb{R}^n \times \mathbb{R}^m \rightarrow \mathbb{R}$ is a convex–concave function (convex in x for every y , and concave in y for every x).

One of the first algorithms proposed for solving such a convex–concave saddle point problem is Arrow–Hurwicz–Uzawa algorithm [10]. This is a gradient-type algorithm that is applicable when the function $L(x, y)$ is differentiable with respect to each of the variables x and y . The algorithm generates a sequence of iterates by taking simultaneous

steps in both variables, as follows: given current iterates x_k and y_k , new iterates are obtained according to the following rule [10]:

$$x_{k+1} = \Pi_X[x_k - \alpha_k \nabla_x L(x_k, y_k)] \\ y_{k+1} = \Pi_Y[y_k - \alpha_k \nabla_y L(x_k, y_k)],$$

where $\alpha_k > 0$ is a stepsize, $\nabla_x L(x_k, y_k)$ is the gradient of L with respect to x evaluated at (x_k, y_k) , and $\nabla_y L(x_k, y_k)$ is the gradient of L with respect to y evaluated at (x_k, y_k) .

There is another popular gradient-based method for saddle point problems when function $L(x, y)$ has Lipschitz continuous gradients $\nabla_x L(x, y)$ and $\nabla_y L(x, y)$. The method is known as *Korpelevich algorithm* [11], also referred to as *extragradient method*.

A convex–concave saddle point problem may also be formulated as a special variational inequality problem, which then may be solved using the algorithms for such problems. For the relation between saddle point problems and variational inequalities, refer to Facchinei and Pang [12] and Konnov [13]. These two references also provide various algorithms for solving variational inequalities such as those arising from saddle point problems. More recently developed algorithms for variational inequalities and saddle point problems can be found in Nemirovski [14], Auslender and Teboulle [15,16], Nesterov [17], and Nedić and Ozdaglar [18]

Algorithms for Dual Problem

The dual problem (2) can be solved provided that the dual function $q(\mu, \lambda)$ can be evaluated (exactly or with a good approximation) at any dual feasible pair (μ, λ) . As discussed earlier, the dual problem (2) is a maximization problem of the concave dual function $q(\mu, \lambda)$ over the convex set $\mathbb{R}_+^m \times \mathbb{R}^r$. Thus, the dual problem is equivalent to convex minimization, and it is often moved to convex minimization framework by setting $F(\cdot) = -q(\cdot)$. Furthermore, the dual function $q(\cdot)$ is typically nondifferentiable [4,5]. For this reason, most of the Lagrangian optimization methods for solving the dual problems have been developed and studied in general form within the

framework of convex nondifferentiable minimization.

In nondifferentiable optimization, a central notion is the notion of a subgradient, which essentially plays the role of a gradient. A definition of a subgradient for a convex function is as follows:

Definition 3 [Subgradient]. A vector $s \in \mathbb{R}^N$ is a subgradient of a convex function $F: \mathbb{R}^N \rightarrow \mathbb{R}$ at the point $\hat{u}$, when the following relation holds:

$$F(\hat{u}) + s^T(u - \hat{u}) \leq F(u) \quad \text{for all } u.$$

The inequality in the subgradient definition basically states that the linear function $\ell(u) = F(\hat{u}) + s^T(u - \hat{u})$, with a fixed $\hat{u}$, underestimates the function $F(u)$ at every point u . Figure 1 gives an illustration of a subgradient of a convex function.

Given a concave function $U(\cdot)$, the function $F(\cdot) = -U(\cdot)$ is convex. Thus, a vector v is a subgradient v of concave $U(u)$ at $u = \hat{u}$ if and only if $s = -v$ is a subgradient of $F(u)$ at $u = \hat{u}$. Formally, a vector v is a subgradient v of concave $U(u)$ at $u = \hat{u}$ if and only if

$$U(\hat{u}) + v^T(u - \hat{u}) \geq U(u) \quad \text{for all } u.$$

In particular, consider the case when the Lagrangian function is given by $\mathcal{L}(x, \mu, \lambda) =$

$f(x) + \mu^T g(x) + \lambda^T Ax$ for $x \in X$. Given a multiplier $(\hat{\mu}, \hat{\lambda})$ such that the dual function value $q(\hat{\mu}, \hat{\lambda})$ is finite, a subgradient of the dual function $q(\mu, \lambda)$ at the point $(\hat{\mu}, \hat{\lambda})$ is given by a vector $(g(\hat{x}), A\hat{x})$, where $\hat{x}$ is a solution of the following problem:

$$\begin{aligned} & \text{minimize } f(x) + \hat{\mu}^T g(x) + \hat{\lambda}^T Ax \\ & \text{subject to } x \in X. \end{aligned}$$

For more details, examples, and a rigorous treatment of subgradients and their properties refer to [4–8, 19, 20].

As mentioned earlier, the methods for solving the dual problems have been studied within the framework of nondifferentiable convex minimization. We adopt this framework for the rest of the discussion.

A subgradient method is one of the simplest algorithms for minimizing a convex nondifferentiable function $F: \mathbb{R}^N \rightarrow \mathbb{R}$ over a convex closed set $\mathcal{X} \subseteq \mathbb{R}^n$. The method takes the following form:

$$u_{k+1} = \Pi_{\mathcal{X}}[u_k - \alpha_k s_k] \quad \text{for all } k \geq 0, \quad (7)$$

where $u_0 \in \mathcal{X}$ is an initial iterate, $\alpha_k > 0$ is a stepsize, and s_k is a subgradient of $F(u)$ at $u = u_k$. The subgradient method of the form (7) has been long studied, and its convergence properties and convergence rate have been

Figure 1. (a) The subgradient property for the epigraph of convex function f : given a subgradient s of f at a point x , the hyperplane in $\mathbb{R}^N \times \mathbb{R}$ with the normal $(s, -1)$ supports the epigraph of a convex function at the point $(x, f(x))$. (b) The subgradient property for the level sets of the function f .

established under various stepsize choices [4,5,8,19,20].

The subgradient method is one of the simplest methods for minimizing a nondifferentiable convex function. Its convergence behavior is very similar to the behavior of gradient methods. In particular, it can be slow just as any gradient algorithm, when the function F has prolonged level sets along some directions. To deal with the slow progress, some modifications of the subgradient method have been considered including those that use space dilation [19].

Unlike gradient methods, the subgradient methods in general *do not have a natural stopping criteria*. Typically, it is run for a pre-specified number of iterations. Also, unlike gradient methods, the subgradient method (7) is *not a descent method*, that is, it does not generate iterates u_k along which the function values $F(u_k)$ necessarily decrease.

There are other subgradient methods that use subgradients to generate descent directions. Some of the descent-based subgradient methods have the same form as in Equation (7), where a descent direction d_k is used in place of a subgradient s_k . The descent direction d_k is obtained by computing several subgradients of F at a given point u_k [4,5, and the references therein].

There is another class of descent-based subgradient algorithms that are more complex. These have been developed starting from the *cutting-plane method* as the basis. The fundamental idea of the cutting-plane method is to generate a sequence of piecewise linear functions F_k , each of which approximates (from below) the given convex function F and the quality of approximation improves as the number k increases. Then, instead of minimizing the function F over the given (closed convex) set $\mathcal{X}$, at each iteration k , the approximate function F_k is minimized over the set $\mathcal{X}$. Formally speaking, at an iteration k , we have the current piecewise linear approximation $F_k(x)$ given by

$$F_k(u) = \max_{0 \leq j \leq k} \left\{ F(u_j) + s_j^T (u - u_j) \right\},$$

where $u_0, u_1, \dots, u_k$ are the iterates generated by the method up to the current time, and s_j is a subgradient of $F(u)$ at $u = u_j$

for all $j = 0, 1, \dots, k$. The next iterate u_{k+1} is determined as a solution to the following minimization problem

$$\begin{aligned} & \text{minimize } F_k(u) \\ & \text{subject to } u \in \mathcal{X}. \end{aligned}$$

The point u_{k+1} is then used to improve the approximate function $F_k(u)$, by computing a subgradient s_{k+1} of $F(u)$ at $u = u_{k+1}$ and, then, defining the approximation $F_{k+1}(u)$ as follows:

$$F_{k+1}(u) = \max \left\{ F_k(u), F(u_{k+1}) + s_{k+1}^T (u - u_{k+1}) \right\}.$$

The new approximate function $F_{k+1}(u)$ is better than the preceding one, $F_k(u)$, in the sense that $F_k(u) \leq F_{k+1}(u)$ for all u . Furthermore, from the subgradient-defining inequality (Definition 3) it can be seen that

$$F_k(u) \leq F(u) \quad \text{for all } u \text{ and } k \geq 0.$$

More discussion on the basic cutting-plane algorithm and its proof can be found in Bertsekas [4,5] (also, see the references therein). The algorithms that build on the cutting-plane method by using analytic center can be found in Kiwiel [21] and Goffin and Vial [22].

More complex descent algorithms that are constructed on the basis of the ideas of the cutting-plane method are known as *bundle methods*. These methods were originally proposed in Kiwiel [23], and further developed in Kiwiel [24], and in Schramm and Zowe [25] where the bundle method is combined with the trust region approach. Bundle methods using a variable metric are discussed in Lemaréchal and Sagastizábal [26], while a quasi-Newton bundle method is given in Mifflin *et al.* [27]. More in-depth coverage of bundle method literature can be found in recent survey papers [22,28].

LARGE DEVIATIONS IN QUEUEING SYSTEMS

AYALVADI J. GANESH
Department of Mathematics,
University of Bristol,
Bristol, UK

BACKGROUND

Queueing theory had its origins in the work of Erlang on telephone networks [1], and has since grown into a branch of operations research with applications in telecommunication and computer networks, manufacturing, service centers, and a number of other areas. In the process, there has been a profusion of mathematical models of queueing networks. The standard approach to obtaining performance measures of queueing systems is to solve for the invariant or equilibrium distribution of the corresponding mathematical model and use that to compute long-run averages of performance measures. However, it turns out that the invariant distribution can only be calculated exactly for a few special queueing models. As a result, practitioners may be faced with a choice between shoehorning the system they are studying into a tractable mathematical model, although the model assumptions are unrealistic for their system, or relying entirely on simulations. Both these choices have their drawbacks. A third alternative is to study asymptotic regimes, in which some “system size” parameter tends to infinity, and in which the model becomes tractable. This approach can be attractive in studying many large systems. Large deviation theory provides one such asymptotic approach.

We begin with a brief review of some widely known results about queueing models. The most classical queueing models are the $M/M/1$ and $M/M/\infty$ queues, in the Kendall notation. (The reader is referred to the encyclopedia articles *The M/G/1 Queue*

and *The M/G/ ∞ Queue*, which include these as special cases.) The queue length process in these two models is a reversible Markov process. This facilitates computation of their invariant distribution, which turns out to be geometric for the $M/M/1$ queue and Poisson for the $M/M/\infty$ queue. The same approach can be used if such queues are connected together in networks with Markovian routing. Such networks are known as *Jackson networks*, and their invariant distribution is of product form. For more details, see the book of Kelly [2]. Unfortunately, this approach only extends to a few special queueing models. Other important examples in this class are $M/GI/1$ -PS and $M/GI/1$ -LCFS-PR queues, with Poisson arrivals, iid service times with general distribution, and a single-server operating either a processor sharing (PS) or last-come-first-served with preemptive resume (LCFS-PR) service discipline, and $M/GI/\infty$ queues. The approach also extends to networks made up of such queues, with Markovian routing between queues. In general, the approach applies to networks that are termed *symmetric queues* [2]. But apart from these few specific models, invariant distributions cannot generally be computed explicitly. In the case of single queues, expressions can be derived for the Laplace transform, or moment-generating function, of the queue length distribution [3], but the techniques involved do not readily generalize to networks.

What can we say more generally about queueing network models? It turns out that, while exact calculations are generally not feasible, results can be obtained for a wide class of models in certain asymptotic regimes. One such regime, which is popular in applications of queueing theory to manufacturing systems, is the heavy-traffic limit. Here, one considers a sequence of systems with, say, the same service time distribution F , but with increasing arrival rate, such that the system is critically loaded in the limit. (By critically loaded, we mean that the rate at which work comes into the system is equal to the rate at

which work can be done.) In this setting, the sequence of queue length processes, suitably scaled, converge to diffusion processes that can be analyzed for a wide range of models.

The heavy-traffic limit is suitable for manufacturing applications, where one typically wishes to operate the system with negligible idling, but it is not appropriate for telecommunication systems. In the latter, it is more common to seek to ensure that blocking or excessive delays are infrequent, even if this requires providing some level of excess capacity. A different asymptotic regime, based on large deviations, is more appropriate in this setting. We give an introduction to large deviations in the next section before we go on to apply it to some queueing models in the following section.

INTRODUCTION TO LARGE DEVIATIONS

Let $X_1, X_2, X_3, \dots$ be a sequence of iid standard normal random variables. Define the partial sums $S_n = \sum_{i=1}^n X_i$. Then S_n/n^α has the normal distribution $N(0, n^{1-2\alpha})$, and a straightforward calculation yields that, for all $\alpha > 1/2$,

$$\begin{aligned} \frac{1}{n^{2\alpha-1}} \log \mathbb{P} \left(\frac{S_n}{n^\alpha} \geq x \right) \\ = \frac{1}{n^{2\alpha-1}} \log \int_x^\infty \sqrt{\frac{n^{2\alpha-1}}{2\pi}} e^{-\frac{n^{2\alpha-1}x^2}{2}} dx \\ \rightarrow \begin{cases} -\frac{x^2}{2}, & x \geq 0, \\ 0, & x < 0. \end{cases} \end{aligned}$$

Let μ_n denote the law of the random variable S_n/n^α . We can then rewrite the above as

$$\frac{1}{n^{2\alpha-1}} \log \mu_n([x, \infty)) \rightarrow -V([x, \infty)),$$

where

$$V([x, \infty)) = \begin{cases} \frac{x^2}{2}, & x \geq 0, \\ 0, & x < 0. \end{cases}$$

The set function V admits a representation as an infimum: $V([x, \infty)) = \inf_{z \in [x, \infty)} I(z)$, where $I(z) = z^2/2$. The above equation says that the

sequence of probability measures μ_n (or random variables S_n/n^α) concentrates around zero at an exponential rate. This is essentially the structure of a large deviation principle, which we now state in a rather general form before considering some concrete examples.

Let E be a Hausdorff space equipped with the topology τ and the corresponding Borel σ -algebra. We say that the sequence of Borel probability measures $\mu_n, n \in \mathbb{N}$ on (E, τ) satisfies a large deviation principle (LDP) with speed a_n and rate function I if there exists a sequence of real numbers a_n such that the inequalities

$$\begin{aligned} -\inf_{x \in B^0} I(x) &\leq \liminf_{n \rightarrow \infty} \frac{1}{a_n} \log \mu_n(B) \\ &\leq \limsup_{n \rightarrow \infty} \frac{1}{a_n} \log \mu_n(B) \leq -\inf_{x \in \bar{B}} I(x) \end{aligned} \quad (1)$$

hold for all Borel sets B . Here, B^0 and $\bar{B}$ denote the interior and closure of B respectively. We say that the rate function I is good if it has compact level sets.

Examples

1. *Cramer's Theorem.* Let $X_1, X_2, \dots$ be a sequence of iid random variables, with associated partial sums $S_n = X_1 + X_2 + \dots + X_n$. The logarithmic moment-generating function of X_1 is defined as

$$\Lambda(\theta) = \log \mathbb{E} \left[e^{\theta X_1} \right], \quad \theta \in \mathbb{R},$$

and takes values in $\mathbb{R} \cup \{+\infty\}$. The convex conjugate of this function is defined as

$$\Lambda^*(x) = \sup_{\theta \in \mathbb{R}} \theta x - \Lambda(\theta),$$

and is also an extended real-valued function. Under these assumptions, the sequence of sample means S_n/n satisfies an LDP on $\mathbb{R}$ (endowed with the usual metric) with speed n and rate function Λ^* , which is a good rate function if Λ is finite in a neighborhood of the origin.

2. *Gärtner–Ellis Theorem.* Let $Y_1, Y_2, \dots$ be a sequence of random variables, with corresponding logarithmic moment-generating functions $\Lambda_n(\theta) = \log \mathbb{E}[\exp(\theta Y_n)]$, and suppose that the limit

$$\Lambda(\theta) = \lim_{n \rightarrow \infty} \frac{1}{n} \Lambda_n(n\theta)$$

exists as an extended real number for all $\theta \in \mathbb{R}$. Suppose, too, that Λ is lower semicontinuous, it is finite in a neighborhood of the origin, differentiable in the interior of its domain, and $\Lambda'(\theta)$ tends to infinity as θ tends to any point on the boundary of the domain of Λ . (The domain is defined as the set on which Λ is finite. The last requirement is termed *steepness*.) Under these assumptions, the sequence of random variables Y_n satisfies an LDP on $\mathbb{R}$ with speed n and good rate function Λ^* .

3. *Borovkov’s and Mogulskii’s Theorems.* We now consider a much more abstract setting. Let $X_1, X_2, \dots$ be an iid sequence of random variables as before. For all $t \in [0, 1]$ and $n \in \mathbb{N}$, let $[nt]$ denote the integer part of nt , and define

$$\begin{aligned} \hat{S}_n(t) &= \sum_{k=1}^{[nt]} X_k, \quad \tilde{S}_n(t) = \hat{S}_n(t) \\ &\quad + (nt - [nt]) X_{[nt]+1}. \end{aligned} \quad (2)$$

Thus, $\hat{S}_n(\cdot)$ is a piecewise constant partial sums process, while $\tilde{S}_n(\cdot)$ is its piecewise linear interpolation. Now $\tilde{S}_n(\cdot)$ lives in the space $C([0, 1])$ of continuous functions on $[0, 1]$, and can be viewed as a random element of this space.

Suppose that $\Lambda(\theta) = \log \mathbb{E}[\exp(\theta X_1)]$ is finite for all $\theta \in \mathbb{R}$. Then, the theorem states that the sequence $\tilde{S}_n(\cdot)/n$ satisfies an LDP on $C([0, 1])$ equipped with the topology of uniform convergence, with speed n , and good rate function

$$\mathcal{I}(\phi) = \begin{cases} \int_0^1 \Lambda^*(\phi'(t)) dt, & \phi \in AC_0([0, 1]), \\ +\infty, & \text{otherwise.} \end{cases}$$

Here ϕ' denotes the derivative of ϕ , and $AC_0([0, 1])$ denotes the space of absolutely continuous functions f on $[0, 1]$ with $f(0) = 0$.

This result was first established by Borovkov for real-valued random variables [4] and extended to $\mathbb{R}^d$ -valued random variables by Mogulskii [5].

The motivating example at the start of this section suggests that the Gaussian random variables S_n/n^α satisfy an LDP (though we only established the bounds in Equation (1) for sets of the form $[x, \infty)$ rather than all Borel sets). This can be formally proved using the Gärtner–Ellis theorem, or Cramer’s theorem in the $\alpha = 1$ case.

The theorems above can be readily extended to random variables X_k that take values in $\mathbb{R}^d$ rather than in $\mathbb{R}$. In this case, the logarithmic moment-generating function is an extended real-valued function defined as $\Lambda(\theta) = \log \mathbb{E}[\exp(\theta \cdot X_1)]$ for $\theta \in \mathbb{R}^d$, where $\theta \cdot X_1$ denotes the inner product of θ and X_1 .

The LDP in Borovkov’s and Mogulskii’s theorems is termed as a *functional LDP* or a *sample path LDP* as it is an LDP for the partial sums process in path space/function space. These theorems can be extended to the space $C([0, \infty))$ (of continuous functions taking values in $\mathbb{R}^d$ for $d \geq 1$) equipped with a suitable topology. First, we can define $\tilde{S}_n(t)$ using Equation (2) for all $t \in \mathbb{R}$ and not just for $t \in [0, 1]$. By the law of large numbers for the iid random variables X_i , we have $\tilde{S}_n(t)/t \rightarrow \mathbb{E}[X_1]$ almost surely as $t \rightarrow \infty$, for each n . Hence, if we define $\mu = \mathbb{E}[X_1]$ and let C^μ denote the subset of $C([0, \infty))$ consisting of all functions f satisfying $f(0) = 0$ and $\lim_{x \rightarrow \infty} f(x)/x = \mu$, then $\tilde{S}_n(\cdot) \in C^\mu$ almost surely. Equip C^μ with the topology induced by the scaled uniform norm,

$$\|\phi\| = \sup_{t \geq 0} \left| \frac{\phi(t)}{1+t} \right|,$$

noting that $\|\phi\|$ is finite for all $\phi \in C^\mu$ since $\phi(t)/t$ tends to a finite limit μ as t tends to infinity. It can be shown that C^μ equipped with this topology is a Polish space. The scaled uniform norm has been used in the study of weak convergence, and was first used

in the large deviations context by Deuschel and Stroock [6].

Now, Borovkov's and Mogulskii's theorems can be strengthened to yield an LDP for the sequence of scaled sample paths $\tilde{S}_n(\cdot)$ on the space C^μ , with good rate function

$$\mathcal{I}(\phi) = \begin{cases} \int_0^\infty \Lambda^*(\nabla\phi(t)) dt, & \phi \in AC_0([0, \infty)) \cap C^\mu; \\ +\infty, & \text{otherwise.} \end{cases}$$

The gradient $\nabla\phi$ is just the derivative ϕ' if the underlying random variables are real-valued. We can relax the assumption that the X_k are iid to suitable mixing conditions. The theorem still holds, with the modification that the term $\Lambda^*(\cdot)$ that appears in the rate function is now defined as

$$\begin{aligned} \Lambda^*(x) &= \sup_{\theta \in \mathbb{R}^d} \theta \cdot x - \Lambda(\theta), \\ \Lambda(\theta) &= \lim_{n \rightarrow \infty} \frac{1}{n} \log \mathbb{E}[\exp(n\theta \cdot \tilde{S}_n(1))]. \end{aligned}$$

The existence of the above limit is part of the assumptions required for the extension to be valid. See Dembo and Zajic [7] for details of the assumptions required to obtain the LDP on $C([0, 1])$, and Ganesh *et al.* [8] for the extension of the LDP to the space C^μ .

In Cramer's theorem, and in the versions of Borovkov's and Mogulskii's theorems that we stated, we scaled the random variables S_n and $\tilde{S}_n$ by n , which is the scaling required to get a law of large numbers or functional law of large numbers, respectively, which has a deterministic limit. Another common scaling involves centering these random variables by subtracting their means, and then scaling by $\sqrt{n}$. This is the central limit scaling (if variances are finite) and yields a stochastic limit, which is either a Gaussian random variable or a Gaussian process. One could instead scale the centered random variable by n^α , for some α between $1/2$ and 1 . (These and more general scalings are considered in the cited papers of Borovkov and Mogulskii.) The resulting sequence of random variables satisfies an LDP with speed smaller than n . Sometimes, the term LDP is reserved for the usual law of large numbers scaling n , and the term moderate deviation principle (MDP) is used for these intermediate scalings

between the law of large numbers and central limit theorem scalings. The distinction is somewhat artificial but not without justification; while the LDP rate function typically depends on the distribution of the random variables involved, the MDP rate function is often quadratic and depends on the random variables only through their variance. To put it another way, fluctuations are usually approximately Gaussian on MDP scales, but there is no such universality on LDP scales.

There are a number of different techniques for establishing LDPs for sequences of random variables, but these are not the subject of this article. The approach that is most relevant to us here is a method for getting new LDPs from old via continuous transformations. It can be seen as an analog of the continuous mapping theorem in weak convergence.

Contraction Principle. Let $\mathcal{X}$ and $\mathcal{Y}$ be Hausdorff topological spaces, and let $f : X \rightarrow Y$ be continuous. Suppose that $(X_n, n \in \mathbb{N})$ satisfy an LDP in $\mathcal{X}$ with speed a_n and good rate function I , and that $Y_n = f(X_n)$. Then, $(Y_n, n \in \mathbb{N})$ satisfy an LDP in $\mathcal{Y}$, with the same speed a_n , and with good rate function

$$J(y) = \inf_{x: f(x)=y} I(x),$$

where the infimum of an empty set is taken to be $+\infty$.

THE SINGLE SERVER QUEUE

We consider a queue operating in discrete time with a single server that serves work in its order of arrival. Let A_n denote the amount of work arriving into the queue in the n th time slot and B_n the amount of work that can be served during this time slot. These may be whole numbers corresponding to numbers of customers, but may more generally be nonnegative real numbers. We assume that $A_n, n \in \mathbb{Z}$ and $B_n, n \in \mathbb{Z}$ are stationary and ergodic stochastic processes.

The results described in this section can be extended to queues operating in continuous time, but we restrict ourselves to the

discrete-time setting for technical simplicity. The discrete-time model could also be justified by considering the queueing process embedded at customer arrival epochs, for instance. Note that we do not assume that interarrival and service times are iid. In many telecommunications applications, there is significant time correlation in these processes, and so the relaxation of independence assumptions is important.

Let W_n denote the amount of work in the queue at the beginning of time slot n . The evolution of W_n is described by Lindley's recursion, which states that

$$W_{n+1} = (W_n - X_n)^+, \text{ where } X_n = A_n - B_n \text{ and } x^+ = \max\{x, 0\}. \quad (3)$$

The recursion simply states that the work in queue at the beginning of time slot $n+1$ is the amount of work that was there at the beginning of time slot n plus the new work that arrived in that time slot, less the amount of work that could have been served, unless more work could have been served than there was in the queue. In the latter case, the queue empties and the amount of work in queue is zero. Implicitly, we think of work as arriving at the beginning of a time slot and being served at the end of the time slot, along with work that is already present.

We assume throughout the following discussion that A_1 and B_1 have finite means, and that $\mathbb{E}[A_1] < \mathbb{E}[B_1]$. This is a standard stability assumption, without which the work in queue tends to infinity over time. Under these assumptions, Loynes [9] showed that Equation (3) has a unique stationary solution. In particular, the solution for W_0 can be written as

$$W_0 = \sup_{n \geq 0} \sum_{k=-n}^{-1} X_k, \quad (4)$$

where an empty sum is taken to be zero by convention. Under the stability assumption, $\mathbb{E}[X_1] < 0$, so the sum on the right-hand side of Equation (4) tends to negative infinity as n tends to infinity, by the law of large numbers. Hence, its supremum is attained at some finite n , almost surely.

Define the process $\tilde{S}_n(t), t \geq 0$ as in Equation (2), with $X_k = A_k - B_k$ as above. Suppose that the process $\tilde{S}_n(\cdot)$ satisfies an LDP on C^μ equipped with the topology induced by the scaled uniform norm, with speed n and with good rate function $\mathcal{I}$. Then, we show that the scaled workload, W_0/n , also satisfies an LDP with the same speed, and identify its rate function under some additional conditions.

The proof of the LDP for W_0/n follows by a straightforward application of the contraction principle. For convenience, we rewrite Equation (4) as

$$W_0 = \sup_{n \geq 0} \sum_{k=1}^n X_k.$$

By the stationarity of the sequence $(X_k, k \in \mathbb{Z})$, the random variable W_0 defined above has the same distribution as the W_0 defined in Equation (4), which is the distribution of the stationary workload in the queue. But the above equation can be rewritten as

$$\frac{W_0}{n} = \sup_{t \geq 0} \tilde{S}_n(t), \quad (5)$$

as the supremum of $\tilde{S}_n$ is necessarily attained at some t such that nt is an integer. Hence, if we can show that the mapping $\phi \mapsto \sup_{t \geq 0} \phi(t)$ is continuous on C^μ , then we can invoke the contraction principle to obtain an LDP for W_0/n .

Recall that $\mu = \mathbb{E}[X_1] < 0$ by the stability assumption. Fix $\phi \in C^\mu$ and $\delta > 0$, and suppose $\psi \in C^\mu$ is such that $\|\phi - \psi\| < \delta$. Now, $\phi(t)/t$ tends to $\mu < 0$ as t tends to infinity, so there is some $T > 0$ such that $\phi(t) < -2\delta$ for all $t > T$. Since $\phi(0) = \psi(0) = 0$ by the assumption that ϕ and ψ are in C^μ , the supremum of ϕ and ψ are both attained on $[0, T]$. But $|\phi(x) - \psi(x)| \leq \delta(1 + T)$ for all $x \in [0, T]$ by the assumption that $\|\phi - \psi\| < \delta$. Hence, if we define $f : C^\mu \rightarrow \mathbb{R}_+$ by $f(\phi) = \sup_{t \geq 0} \phi(t)$, then we have shown that $|f(\phi) - f(\psi)| \leq \delta(1 + T)$ for all ψ such that $\|\phi - \psi\| < \delta$, where T is a constant that depends only on ϕ . This shows that f is continuous.

Since $W_0/n = f(\tilde{S}_n)$, it immediately follows from the contraction principle and the assumed LDP for $\tilde{S}_n$ that W_0/n satisfies an

LDP on $\mathbb{R}_+$ at speed n , and that the rate function for this LDP is given by

$$\begin{aligned} J(x) &= \inf_{\phi \in C^\mu: f(\phi)=x} \mathcal{I}(\phi) \\ &= \inf \left\{ \mathcal{I}(\phi) : \phi \in C^\mu, \sup_{t \geq 0} \phi(t) = x \right\}. \end{aligned} \quad (6)$$

The rate function J is thus given as the solution of a variational problem. If the rate function $\mathcal{I}$ is of the form

$$\mathcal{I}(\phi) = \int_0^\infty \Lambda^*(\phi'(t)) dt,$$

for a convex function Λ^* that takes its minimum value of 0 uniquely at μ (as is the case with the extension of Mogulskii's theorem discussed above), then we can reduce the variational problem in Equation (6) to a finite-dimensional optimization problem. It can be shown, using the convexity of Λ^* and Jensen's inequality, that the infimum in Equation (6) is attained by a ϕ that is piecewise linear, and of the form

$$\phi(t) = \begin{cases} \alpha t, & 0 \leq t \leq T, \\ \mu(t - T), & t > T, \end{cases}$$

for constants $\alpha > 0$ and $T > 0$, which are obtained by solving the finite-dimensional optimization problem stated below. The rate function J can be expressed in terms of its solution, as follows:

$$\begin{aligned} J(x) &= \min_{\alpha, T > 0: \alpha T = x} T \Lambda^*(\alpha) \\ &= x \min_{\alpha > 0} \frac{\Lambda^*(\alpha)}{\alpha}. \end{aligned} \quad (7)$$

Observe that the rate function is linear in x . The LDP implies that $\mathbb{P}(W_0 > w) \approx e^{-wJ(1)}$ for large w . More precisely, the two sides are logarithmically equivalent as w tends to infinity, that is,

$$\lim_{w \rightarrow \infty} \frac{1}{w} \log \mathbb{P}(W_0 > w) = -J(1). \quad (8)$$

The result thus provides quite general conditions under which the distribution of the work in queue has exponential tails, even for arrival and service processes that may show

a considerable degree of time dependence. Conditional on the build-up of a large workload w , the optimization problem in equation (7) also provides information about the most likely trajectory by which the workload built up. It says that the most likely trajectory involved the queue building up at constant rate α for a time period of length Tw , where α and T achieve the minimum for $J(1)$. Thus, the rate of queue build-up α does not depend on w , while the length of time over which the queue builds up scales linearly in w .

The asymptotic regime in Equation (8) is sometimes referred to as the *large buffer asymptotic*, as it describes the probability of the contents of the queue exceeding the capacity of a large buffer. This is one of the regimes of interest in a communication network, where the buffer stores data at the ingress of a network link. Another regime of interest is the so-called many flows regime, where the input (arrival process) is treated as the superposition of a large number of iid arrival processes, and the service capacity scales linearly in this number. The study of this regime is quite similar to that of the large buffer regime. It involves using a sample path LDP for the aggregate arrival process scaled by the number of superposed flows. Thus, the scaling here is over space (number of flows, n) rather than time (aggregate arrivals over a period of length nt), but the approach is otherwise similar and involves the use of the contraction principle. (The map from the arrival process to the queue size is identical, and hence is continuous in the topology induced by the scaled uniform norm.) The main difference is that the rate function for the scaled queue length need not be linear in this regime. The reader is referred to Ganesh *et al.* [8] for details, both for the many flows scaling regime and for moderate deviation scalings.

DISCUSSION

This article aimed to provide an elementary introduction to large deviations theory, and to its application in queueing systems. It only treated the very simple case of a FIFO queue with a single server, albeit with

quite general arrival and service processes. Despite the generality of the driving processes considered, this is still the simplest and most classical queueing model. It would be natural to ask if large deviation techniques permit the treatment of a much wider class of queueing models. In particular, can they be applied to both single and multiclass queues implementing a variety of different service disciplines including processor-sharing and priority-based disciplines? Can they also be applied to networks of queues?

The general answer is that progress has been quite slow and piecemeal. While there is an elegant unifying framework based on establishing the continuity of queueing maps and employing the contraction principle, the details of carrying out these steps pose considerable challenges, which have to be tackled using different techniques in different models. One of the problems is that the queueing maps of interest may not satisfy the strict continuity assumptions described here. In some instances, generalizations of the contraction principle based on Garcia [10] and Puhalskii [11] can be used to obtain an LDP [12]. Another common difficulty is that, while continuity may be established and the existence of an LDP deduced thereby, the variational problem describing the rate function turns out to be intractable. One is then forced to turn to bounds and approximations.

The field continues to provide a rich source of open problems, of both a mathematical and an applied nature, motivated by communication and computer networks, by new scheduling and routing algorithms, and by new application domains such as wireless communications.

LARGE MARGIN RULE-BASED CLASSIFIERS

TIBÉRIUS O. BONATES
Princeton Consultants, Inc.,
Princeton, New Jersey

INTRODUCTION

In this article, we present an optimization approach for the construction of rule-based classification models, with a focus on logical analysis of data (LAD).

The main idea behind LAD is to create a relevant set of logical rules (called *patterns*) that can collectively be used for classification. Each pattern consists of one or more conditions on the values of features such as “*feature 1 = 0*” or “*feature 3 ≥ 3.2*.” LAD is usually applied to two-class classification problems via a system of weights that assigns a positive weight to patterns that are characteristic of one of the two classes, and a negative weight to patterns that are characteristic of the opposite class. For any given point, its classification according to LAD is given by the total weight obtained by adding up the individual weights of the patterns, whose defining conditions hold on at that point.

Constructing a set of patterns that accurately characterizes the two classes, and properly assigning weights to these patterns in order to obtain a robust classification of unseen points, is crucial for the application of LAD to any given data set. Different algorithms have been proposed for the construction of specific families of patterns [1–4]. Similarly, different approaches have been evaluated for assigning weights to patterns [5,6].

Our algorithm utilizes a clear performance criterion that guides the search for a set of patterns (or rules), reducing the need for a careful calibration of a number of control parameters, as is typically the case with

most classification methods. Moreover, our algorithm automatically adjusts the weights assigned to these patterns while optimizing the performance criterion, accomplishing in a single effort, the distinct tasks of pattern generation and selection of a set of weights defining a robust classifier.

The article is organized as follows: in the section titled “LAD Patterns and Classifiers,” we review the main concepts in LAD. The section titled “Large Margin LAD Classifiers” describes the concept of large margin LAD classifiers and the optimization model, which is the basis of our algorithm. In the section titled “Pricing Subproblem,” we describe the optimization subproblem used to construct patterns as part of our iterative optimization algorithm, which is discussed at length in the section titled “Column Generation Algorithm.” Finally, the section titled “Conclusions” summarizes our results and suggests future research directions.

LAD PATTERNS AND CLASSIFIERS

Consider a binary data set $\Omega \subset \{0, 1\}^n$ consisting of two disjoint sets of positive and negative points, that is, $\Omega = \Omega^+ \cup \Omega^-$, with $\Omega^+ \cap \Omega^- = \emptyset$. While we assume that Ω is a binary data set, the ideas described in this article can be applied to data sets with numerical attributes via the use of a discretization procedure. As part of the standard practice of applying LAD to a data set, a discretization step is carried out according to the method described in Ref. 5. For an overview of some commonly used discretization procedures the reader is referred to Ref. 7.

Patterns

A *pattern* or *rule* is simply a homogeneous subcube of $\{0, 1\}^n$, that is, a subcube having (i) a nonempty intersection with one of the sets Ω^+ or Ω^- , and (ii) an empty intersection with the other set (Ω^- or Ω^+ , respectively). We recall that a subcube consists of those points of the n -cube for which a subset of

the variables is fixed to 0 or 1, while the remaining variables take all the possible 0, 1 values. A pattern P disjoint from Ω^- is called a *positive pattern*, while a pattern N disjoint from Ω^+ is called a *negative pattern*. A point in $\{0, 1\}^n$ is said to be *covered* by a pattern if it belongs to the subcube defined by that pattern.

In the remainder of this article, we will use a relaxed definition of a pattern, in which a positive pattern is allowed to cover some negative points. Similarly, a negative pattern is allowed to cover some positive points. Traditionally, the number of points of the opposite type that a pattern is allowed to cover is controlled by parameters called *homogeneity* or *fuzziness* [1,3,4]. In this article, we will refrain from defining such parameters, since our algorithm does not directly consider these values, but instead implicitly considers *all* possible patterns.

A positive (or negative) pattern can be thought of simply as a realization of a subset of the components in our data set that is characteristic of the Ω^+ (or Ω^-) set. A pattern is typically expressed as a Boolean conjunction such as $P = \prod_{i \in A} x_i \prod_{j \in B} \bar{x}_j$, where x_i is a Boolean literal corresponding to the i th component of the data set, and $\bar{x}_j$ is the associated negated literal. The literal x_i is considered satisfied by a certain point $\omega \in \{0, 1\}^n$ if and only if $\omega_i = 1$. Conversely, $\bar{x}_j$ is satisfied if and only if $\omega_j = 0$. A literal is considered to have a value of 1 if it is satisfied, and a value of 0 otherwise.

Models and Discriminant Functions

An *LAD model* consists of a set M of positive and negative patterns, so that every point in Ω^+ is covered by at least one of the positive patterns in M , and every point in Ω^- is covered by at least one of the negative patterns in M . The construction of an LAD model is a computationally expensive task that typically involves the enumeration of a large set of patterns satisfying a certain property, followed by the selection of a relatively small subset of those [1,8,3].

The fact that only a fraction of the patterns generated is ultimately used for the construction of an LAD model suggests that the approach described above

for model construction may not be the most efficient one. Moreover, the choice of enumerating a specific family of patterns, and the usual selection of a small number of those patterns—which is frequently guided by a greedy criterion—may not be the most appropriate for certain problems, resulting in suboptimal LAD models. In view of this, it is appropriate to say that there is a clear need for a global criterion for choosing an overall “best” LAD model.

Given an LAD model $M = M^+ \cup M^-$ (where M^+ is a set of positive patterns and M^- is a set of negative patterns) and a point $\omega \in \{0, 1\}^n$, the classification of ω is determined by the sign of a so-called *discriminant function* $\Delta : \{0, 1\}^n \rightarrow \mathbb{R}$ associated to the given model. Let $M^+ = \{P_1, \dots, P_{|M^+|}\}$ and $M^- = \{N_1, \dots, N_{|M^-|}\}$, and let us associate to each positive pattern $P_i \in M^+$, a real weight α_i and to each negative pattern $N_j \in M^-$ a real weight β_j . The associated discriminant function on ω is given by

$$\Delta(\omega) = \sum_{P_i \in M^+} \alpha_i P_i(\omega) - \sum_{N_j \in M^-} \beta_j N_j(\omega),$$

where $P_i(\omega)$ equals 1 if ω is covered by P_i , and 0 otherwise (similarly for $N_j(\omega)$). The sign of $\Delta(\omega)$ determines the classification of ω . If $\Delta(\omega) = 0$ the observation is either left unclassified, or is classified according to the more frequent class.

For a given set of patterns, the construction of a discriminant function for classification is usually done either by majority vote among positive and negative patterns (i.e., by assigning equal weights among positive and among negative patterns), or by solving a linear program that provides a set of weights resulting in an optimal separation of the two classes (as described in Ref. 6). In the next section, we will describe a formulation based on the linear program of Ref. 6, which finds an optimal discriminant function defined over the set of all patterns.

LARGE MARGIN LAD CLASSIFIERS

It is important to develop an algorithm that selects a set of patterns and a set of weights

to build an optimal discriminant function according to a certain performance criterion that relates to the generalization of the classifier. A natural criterion is the *separation margin* of the classifier [9,10]. In the context of LAD, the separation margin is simply the difference between the smallest value that the discriminant function takes over the positive points of the training set that are correctly classified and the largest value that the discriminant function takes over the negative points in the training set that are correctly classified. Thus, the separation margin corresponding to a given discriminant function is

$$\min\{\Delta(\omega) : \omega \in \Omega^+, \Delta(\omega) > 0\} \\ - \max\{\Delta(\omega) : \omega \in \Omega^-, \Delta(\omega) < 0\}.$$

By maximizing the separation margin, we expect a robust classification of unseen examples. This expectation has been confirmed in practice in many situations [11–13]. The good performance of boosting and voting-based classifiers has also been shown to be related to the implicit maximization of the separation margin of the resulting classifier [13].

Linear Programming Formulation

In what follows, we show how to formulate the problem of constructing an optimal discriminant function by using a linear programming formulation, similar to the one described in Ref. 6. This linear programming formulation involves a very large number of variables and is shown to be amenable to a solution via column generation [14–17].

Let $\mathbb{P} = \{P_1, \dots, P_{|\mathbb{P}|}\}$ be the set of *all* positive patterns, and let $\mathbb{N} = \{N_1, \dots, N_{|\mathbb{N}|}\}$ be the set of *all* negative patterns. We are interested in solving the following problem:

$$(P) \quad \text{maximize} \quad r + s - C \sum_{\omega \in \Omega} \epsilon_{\omega}$$

subject to:

$$\sum_{i=1}^{|\mathbb{P}|} \alpha_i P_i(\omega) - \sum_{j=1}^{|\mathbb{N}|} \beta_j N_j(\omega) + \epsilon_{\omega} \geq r, \quad \forall \omega \in \Omega^+; \quad (1)$$

$$\sum_{i=1}^{|\mathbb{P}|} \alpha_i P_i(\omega) - \sum_{j=1}^{|\mathbb{N}|} \beta_j N_j(\omega) - \epsilon_{\omega} \leq -s, \\ \forall \omega \in \Omega^-, \quad (2)$$

$$\sum_{i=1}^{|\mathbb{P}|} \alpha_i = \sum_{j=1}^{|\mathbb{N}|} \beta_j = 1,$$

$$r \geq 0, s \geq 0$$

$$\alpha_i \geq 0, i = 1, \dots, |\mathbb{P}|, \beta_j \geq 0, j = 1, \dots, |\mathbb{N}|$$

$$\epsilon_{\omega} \geq 0, \forall \omega \in \Omega,$$

where the values of α_i ($i = 1, \dots, |\mathbb{P}|$) and β_j ($j = 1, \dots, |\mathbb{N}|$) are the weights of the positive and negative patterns, respectively, r represents the positive part of the separation margin, s represents the negative part of the separation margin, and C is a nonnegative penalization parameter that controls how much importance is given to the violations ϵ_{ω} of the separating constraints of Equations (1) and (2).

Owing to the potentially very large total number of patterns, it is highly unlikely that in real-world applications one will encounter a data set, where such a formulation can be directly tackled. Thus, let us consider a subset of positive patterns $\mathcal{P}^0 \subset \mathbb{P}$ and a subset of negative patterns $\mathcal{N}^0 \subset \mathbb{N}$, and let us denote by $I^0 \subset \{1, \dots, |\mathbb{P}|\}$ and $J^0 \subset \{1, \dots, |\mathbb{N}|\}$ the sets of indices corresponding to the elements of $\mathcal{P}^0$ and $\mathcal{N}^0$, respectively. Then, we can write a restricted version of (P) as

$$(RP) \quad \text{maximize} \quad r + s - C \sum_{\omega \in \Omega} \epsilon_{\omega}$$

subject to:

$$r - \sum_{i \in I^0} \alpha_i P_i(\omega) + \sum_{j \in J^0} \beta_j N_j(\omega) - \epsilon_{\omega} \leq 0, \\ \forall \omega \in \Omega^+, \quad (3)$$

$$s + \sum_{i \in I^0} \alpha_i P_i(\omega) - \sum_{j \in J^0} \beta_j N_j(\omega) - \epsilon_{\omega} \leq 0, \\ \forall \omega \in \Omega^-, \quad (4)$$

$$\sum_{i \in I^0} \alpha_i = 1, \quad (5)$$

$$\sum_{j \in J^0} \beta_j = 1, \quad (6)$$

$$r \geq 0, s \geq 0$$

$$\alpha_i \geq 0, \forall i \in I^0, \beta_j \geq 0, \forall j \in J^0,$$

$$\epsilon_\omega \geq 0, \forall \omega \in \Omega.$$

Note that we rearranged constraints (3) and (4) in order to write RP (i.e., the restricted version of P) in a standard maximization form.

It is easy to choose $\mathcal{P}^0$ and $\mathcal{N}^0$ in such a way that RP has a feasible solution. We recall that the *minterm* corresponding to a given point ω is simply the pattern with the largest possible number of literals that is satisfied by ω , that is, it is the pattern given by the following conjunction: $T = \prod_{i:\omega_i=1} x_i \prod_{j:\omega_j=0} \bar{x}_j$. Clearly, T is a pattern that covers ω and does not cover any observation from the opposite part of the data set (since $\Omega^+ \cap \Omega^- = \emptyset$). Let us choose $\mathcal{P}^0$ and $\mathcal{N}^0$ to be the sets of minterms corresponding to the positive and negative observations in the data set, respectively. Then, the vectors α and β are given by $\alpha_i = \frac{1}{|\mathcal{P}^0|}$, $i \in \mathcal{P}^0$ and $\beta_j = \frac{1}{|\mathcal{N}^0|}$, $j \in \mathcal{N}^0$, along with $r = \frac{1}{|\mathcal{P}^0|}$, and $s = \frac{1}{|\mathcal{N}^0|}$ constitute a feasible solution to RP. As we have just showed, constructing a feasible set of patterns to initialize RP is not a difficult task; as a matter of fact, one pattern of each class would suffice.

It is advantageous, however, to find a set of good quality patterns with which to initialize the column generation algorithm as such patterns are likely to be part of the optimal solution and their use in early iterations may significantly speed up the entire procedure. (This should become clearer once we describe the column generation algorithm in a separate section). On the other hand, spending a considerable amount of time to generate patterns of good quality defeats the purpose of running our algorithm to automatically search for the best set of patterns for classifying the training data. In the experiments reported in the section

titled “Column Generation Algorithm,” we adopt a compromise by initializing our algorithm with the set of patterns consisting of single literals $\{x_1, \dots, x_n\}$. This amounts to attempting a linear separation using the original features of the data set. While this is not a sophisticated initial set of patterns, it is more likely that some of these patterns will be used in the optimal classifier than some of the minterms, which are clearly less descriptive of the data set as a whole.

PRICING SUBPROBLEM

In this section, we address the subproblem phase in the column generation algorithm. We formulate this problem as a pseudo-Boolean optimization problem that can also be seen as a weighted version of the *maximum pattern problem* [4,18].

The solution to the problem (RP) provides an optimal discriminant function for the set of patterns $\mathcal{P}^0 \cup \mathcal{N}^0$. However, that discriminant function may not be optimal with respect to the entire set of all patterns. In order to verify global optimality, we need to make sure that there is no pattern that once added to the current set of patterns, allows for an improvement in the value of the objective function of RP.

In the simplex method, one of the commonly used heuristics for choosing a nonbasic variable to enter the current basis is to choose the variable with the best (in the maximization case, the largest) reduced cost [19–22]. Similarly, we use the reduced cost of a specific pattern P to measure the potential improvement in the objective function of RP resulting from the introduction of P into the set of known patterns $\mathcal{P}_0 \cup \mathcal{N}_0$. To verify the optimality of the current solution of RP, we solve a pricing problem that will return a pattern with the best (largest) reduced cost with respect to the current values of the dual variables of RP.

According to the usual optimality criterion of the primal simplex method, if there is no pattern (not in $\mathcal{P}^0 \cup \mathcal{N}^0$) with a nonnegative reduced cost, then the current solution of RP is optimal to P; otherwise, a new pattern

can be added to the set $\mathcal{P}^0 \cup \mathcal{N}^0$ and the algorithm proceeds. Notice here that we allow the introduction of a pattern whose reduced cost is zero. Since the column generation algorithm is equivalent to applying the simplex algorithm to a large formulation, there is a possibility of having degenerate iterations in which no progress is made in terms of the objective function [19–22]. We will refer to a pattern with nonnegative reduced cost at a given iteration as a *candidate pattern*.

Note that since $r + s$ corresponds to the separation margin of the current discriminant function, solving the pricing problem corresponds to asking if the current separation margin can be enlarged by the addition of a pattern. Thus, the column generation algorithm applied to problem P attempts to increase the separation margin by including patterns that make the distinction between the sets Ω^+ and Ω^- more pronounced.

From now on, let us assume that k iterations of the column generation algorithm have been executed. We will refer to the corresponding sets of patterns as $\mathcal{P}^k$ and $\mathcal{N}^k$, and to the corresponding version of problem RP as RP^k . Let λ and μ be the vectors of dual variables associated with constraints (3) and (4), respectively, at an optimal solution of RP^k . Similarly, let θ^+ and θ^- be the dual variables corresponding to constraints (5) and (6). The reduced costs [19–22] corresponding to a positive pattern P_i and a negative pattern N_j are given by $\theta^+ + [\lambda^\top, -\mu^\top]\pi_i$ and $\theta^- + [-\lambda^\top, \mu^\top]v_j$, respectively, where $\pi_i = [P_i(\omega)]_{\omega \in \Omega^+}$ and $v_j = [N_j(\omega)]_{\omega \in \Omega^-}$ are the characteristic vectors of the observations covered by P_i and N_j , respectively.

Formulation

Let us define binary decision variables x_i and x_i^c ($i = 1, \dots, n$) associated with attribute a_i in the following way: (i) $x_i = 1$ and $x_i^c = 0$ if the literal associated to $a_i = 1$ is used in the resulting pattern; (ii) $x_i = 0$ and $x_i^c = 1$ if the literal associated with $a_i = 0$ is present in the resulting pattern. Thus, the positive pricing subproblem associated to optimal vectors of dual variables λ^* and μ^* of RP can be formulated as the following pseudo-Boolean

optimization problem:

$$\begin{aligned} (\text{SP}^+) \quad & \text{maximize} \sum_{\omega \in \Omega^+} \lambda_\omega^* \left(\prod_{i:\omega_i=0} \bar{x}_i \prod_{j:\omega_j=1} \bar{x}_j^c \right) \\ & - \sum_{\omega \in \Omega^-} \mu_\omega^* \left(\prod_{i:\omega_i=0} \bar{x}_i \prod_{j:\omega_j=1} \bar{x}_j^c \right) \end{aligned} \quad (7)$$

subject to:

$$x_j, x_j^c \in \{0, 1\}, \quad j = 1, \dots, n,$$

where each term $\prod_{i:\omega_i=0} \bar{x}_i \prod_{j:\omega_j=1} \bar{x}_j^c$ takes the value 1 whenever ω is covered by the resulting conjunction, and 0 otherwise.

Problem (SP^+) belongs to the family of pseudo-Boolean optimization problems, whose solution was addressed in Ref. 23. In our computational experiments, we utilized the branch-and-bound algorithm described in Ref. 23 to solve (SP^+) .

Note that since the value of the dual variable θ^+ appears as a constant term in the reduced cost formula, it is not required in the formulation of SP^+ . Also, by solving SP^+ , we aim at constructing a positive pattern, and therefore, it is implicit that the column corresponding to such a pattern has a coefficient equal to 1 in the row corresponding to constraint (5) and a coefficient equal to 0 in the row corresponding to constraint (6).

While SP^+ is aimed at finding the best positive candidate pattern at the current iteration, it may be necessary to search for a negative candidate pattern as well. In fact, even if we have already found a positive candidate pattern, it may be advantageous to generate a negative candidate pattern, if there is any. We suggest solving both SP^+ and its negative counterpart SP^- . For the negative pricing problem SP^- , we simply minimize the same objective function as in problem SP^k , as opposed to maximizing it in SP^+ .

The solutions of SP^+ and SP^- provide either: (i) a certificate of optimality of the current discriminant function, in case the objective function value of SP^+ is strictly negative and that of SP^- is strictly positive; or (ii)

-
1. Input: Ω^+, Ω^- , initial sets $\mathcal{P}^0$ and $\mathcal{N}^0$ of patterns. Set $k = 0$.
 2. Solve $(\text{RP}(k))$, with optimal primal and dual solutions $(r^*, s^*, \alpha^*, \beta^*)$ and $(\lambda^*, \mu^*, \theta^{+*}, \theta^{-*})$.
 3. Solve $(\text{SP}(k)^+)$ and $(\text{SP}(k)^-)$, with optimal positive and negative patterns P^* and N^* .
 4. If at least one of the stopping criteria is met, stop.
 5. If P^* or N^* (or both) are candidate patterns, define $\mathcal{P}^{k+1} = \mathcal{P}^k \cup \{P^*\}$ and $\mathcal{N}^{k+1} = \mathcal{N}^k \cup \{N^*\}$ accordingly, and set $k = k + 1$.
 6. Go to Step 2.

a new positive or negative pattern (or both) to be added to our current set of known patterns. In general, if at iteration k , we generate new patterns $P^* \in \mathbb{P}$ and $N^* \in \mathbb{N}$, then we define the sets of patterns for the next iteration as $\mathcal{P}^{k+1} \leftarrow \mathcal{P}^k \cup \{P^*\}$ and $\mathcal{N}^{k+1} \leftarrow \mathcal{N}^k \cup \{N^*\}$.

COLUMN GENERATION ALGORITHM

The column generation algorithm as described above alternates the solution of problem RP with the solution of SP^+ and SP^- . While problem RP optimizes the discriminant function over the current set of patterns, problems SP verify the optimality of the discriminant function obtained by RP and, if necessary, produce new patterns to improve the current discriminant function. Thus, the iterative process stops at one of the following events: (i) the maximum number of iterations is reached; (ii) no candidate pattern can be found; (iii) no significant improvement of the objective function of RP takes place after a certain number of iterations. For the latter case, we need to define two control parameters: a tolerance value corresponding to the smallest increase in the objective function of RP to be regarded as a significant increase, and the maximum number of iterations to be allowed without a significant increase. These control parameters are important since in practice, it is possible to have long sequences of iterations in which the objective function of RP remains unchanged or changes only slightly.

Although column generation algorithms usually approach the neighborhood of a near-optimal solution in a reasonably small number of iterations [16,21], achieving or proving

optimality may take a very large number of iterations. Typically, toward the end of the algorithm's execution, the graph corresponding to the progress in the objective function value exhibits a long "tail," reflecting the failure in making significant progress during a large number of iterations. This phenomenon is known as the *tailing-off effect* [15–17,20,21]. In our experiments, we used the tolerance parameter equal to 10^{-4} and the maximum number of degenerate iterations equal to 10. The maximum number of iterations allowed for the entire execution of the algorithm was set to 1000, but was never reached in our experiments.

Figure 1 summarizes the algorithm. We use the notation $\text{RP}(k)$, $\text{SP}(k)^+$ and $\text{SP}(k)^-$ to denote the optimization problems solved at iteration k .

Computational Experiments

The algorithm proposed in this study was implemented in C++, using the *MS Visual C++ .NET 1.1* compiler. The linear programming formulations solved as part of the column generation algorithm were solved using the callable library of the Xpress-MP optimizer [24]. The computer used for carrying out the experiments reported here was an *Intel Pentium*[®] 4, 3.4 GHz, with 2 GB of RAM.

Problems SP^+ and SP^- were not necessarily solved to optimality in our experiments. Given the satisfactory performance of the truncated versions of the branch-and-bound algorithm proposed in Ref. 23, we established an explicit limit of 3000 branch-and-bound nodes per problem.

Figure 2. Histograms of observations at different discriminant levels for the “heart” data set: (a) at iteration 2, (b) at iteration 5, (c) at iteration 10, (d) at iteration 20, (e) at iteration 50, and (f) at iteration 72.

In Fig. 2, we show six histograms illustrating a typical example of how the frequencies of values of the discriminant function evolve during the execution of our algorithm. The graphs correspond to the application of our

training algorithm to a randomly extracted sample of 90% of the observations in the “heart” data set, from the UCI Repository [25]. The empty region in the middle of the graphs is the separation margin between

Figure 3. Behavior of the positive and negative margins for the “heart” data set.

positive and negative points. The graphs show how our algorithm iteratively improves the separation margin as it finds candidate patterns and adjusts the weights of the discriminant function accordingly.

Although all observations are correctly separated in each of the iterations, we can see that a large number of observations are on the border of the separating region in early iterations; that is, their corresponding constraints from sets (3) and (4) are binding. The observations on the border of the margin of separation can be seen as “support observations,” just as in the case of support vector machines [10,26].

In Fig. 3, we present the values of the positive and negative margins during the execution of the same experiment on the “heart” data set. It is important to notice that while the individual (positive and negative) margins do not vary monotonically with the number of iterations, the difference between the positive and the negative margin is monotonically nondecreasing with respect to the number of iterations. It can also be seen that roughly after iteration 50, the algorithm stops making significant improvements in the separation margin. This observation helped us to adjust the parameters for early termination that prevent the tailing-off phenomenon and avoid overfitting the discriminant function to the training sample.

Table 1 reports the accuracy of five algorithms implemented in the Weka package, the maximum patterns-based LAD version described in Ref. 4 (termed *CAP-LAD*), and those of LAD models built utilizing the algorithm described in this article (termed *LM-LAD*, for large margin logical analysis of data). The Weka algorithms utilized are the following: SMO, support vector machines; J48, C4.5 decision trees; RF, random forests; MP, multilayer perception; and SL, simple logistic regression.

The data sets used in Table 1 were obtained from the UCI Machine Learning Repository [25]. The reported accuracies were calculated as the average result of one random 10-fold cross-validation experiment with a 95% confidence interval (see Refs 27 and 28 for additional information on standard procedures for cross-validated experiments). In order to apply the LAD algorithms to these data sets, each training set in the cross-validation procedure was discretized [as described in Ref. 5], and the same discretization utilized for the purpose of classifying the test set. We display the highest accuracy for each data set in boldface characters. Moreover, at the bottom of the table, we display the so-called *Borda count* [29] of each algorithm. The Borda count in Table 1 is obtained by ranking the seven algorithms based on their accuracies on a

given data set. The most accurate algorithm is assigned a score of 7, the second best is assigned a score of 6, and so on until a score of 1 is assigned to the algorithm with the worst accuracy on that data set. The Borda count of an algorithm is the sum of these scores over the 10 data sets, and summarizes its comparative performance.

In Table 2, we present the counts of wins, losses, and ties for the pairwise comparison of the seven algorithms. Each pairwise comparison in Table 2 is made with respect to the 95% confidence interval presented in Table 1.

While being superior to some of the other algorithms for some data sets, the performance of the LM-LAD algorithm is, strictly speaking, generally inferior to that of other algorithms on the data sets used in our experiments. The Borda count shown in Table 1 summarizes this observation. However, the accuracies obtained by our algorithm are reasonably close to those of the other algorithms (as can be seen from Table 2). Indeed, as discussed in Ref. 28, the direct comparison of the accuracy of two algorithms in the experimental setup utilized here must be regarded cautiously, while the conclusion that the two accuracies are not statistically different is to be trusted. Moreover, if, for each data set, we compare the accuracy of LM-LAD with the highest accuracy of the other six algorithms, we can see that LM-LAD achieves on average 94.3% of the accuracy of the best algorithm.

It is important to mention that the six-type classification of algorithms used for comparison was extensively calibrated for the data sets used in our experiments. Indeed, most machine learning algorithms would require a careful calibration of their parameters in order to provide accurate cross-validation results as the ones shown in Table 1. On the other hand, the LM-LAD algorithm had its single parameter C fixed at 1 in all experiments reported in Table 1. We performed experiments with different values of the C parameter, reaching the conclusion that it had a minimal effect on the accuracy of the resulting models for the data sets under consideration.

CONCLUSIONS

We described a novel algorithm for constructing a large margin classifier consisting of the combination of LAD patterns (or rules, in a more general sense). Our algorithm is based on a linear programming optimization model, solved via the classical column generation procedure. The most important feature of our algorithm resides in the fact that it requires the calibration of a single control parameter, unlike most machine learning methods, which normally require substantial calibration. The classifiers produced by our algorithm were shown to provide accurate cross-validated results, comparable to those produced by carefully calibrated implementations of standard machine learning algorithms.

While our algorithm relies on a simple linear programming formulation, we believe that the use of different objective functions could further improve the quality of the resulting classifiers. This notion is supported by the fact that our algorithm can also be easily modified to solve regression problems, as described in Ref. 30. Also, a more conservative way of generating patterns by imposing limits on their *homogeneities* and coverages—as is traditionally the case in LAD [1,3,4]—could prove beneficial in terms of accuracy, while incurring the need for additional calibration.

Finally, we would like to remark that our algorithm can be applied in conjunction with any rule-based classification algorithm. Our column generation algorithm can be seen as a high-level procedure for creating a weighted combination of classifiers with the purpose of maximizing the margin of separation. Indeed, the pricing subproblem is the only step in our description, which is directly related to LAD. By replacing the construction of *candidate patterns* with the construction of *candidate rules*, we can use precisely the same framework for creating a classifier comprised of a weighted combination of generic rules.

LATIN–IBERO–AMERICAN ASSOCIATION FOR OPERATIONAL RESEARCH

HÉCTOR CANCELA

Departamento de Investigación Operativa,
Instituto de Computación, Facultad de
Ingeniería, Universidad de la República,
Montevideo, Uruguay

The Latin–Ibero–American Association for Operational Research, usually known as *Asociación Latino–Ibero–Americana de Investigación Operativa* (ALIO) is the association of the national operational research societies in Latin America and the Iberian Peninsula.

The main objectives of ALIO are to promote the progress and application of operational research (OR) in the region, and to support the networking and free exchange of information among academicians, professionals, and decision makers in the region. Also, ALIO plays an important role as the regional grouping for the Latin–American region within IFORS, the International Federation of Operational Research Societies.

ALIO was born in 1982, after an initiative of Nelson Maculan (Brazil), Hugo Scolnik (Argentina), and Andrés Weintraub (Chile), who, meeting at an event in Rio de Janeiro in 1981, foresaw the need to create an organization which would appeal to all researchers working in the OR field in different countries in the region, so that they could work together to strengthen the community and make it grow. In 1982, the association was officially founded, and its initial Executive Committee elected, at the occasion of the first CLAIO, Latin–Ibero–American Operational Research Conference, which has since been organized biennially.

The list of past presidents of ALIO and their terms of office are as follows:

- 1982–1984 Roberto Galvão (Brazil);
- 1984–1986 Héctor Monteverde (Argentina);

- 1986–1988 Andres Weintraub (Chile);
- 1988–1990 Nelson Maculan (Brazil);
- 1990–1992 Hugo Scolnik (Argentina);
- 1992–1994 Celso C. Ribeiro (Brazil);
- 1994–1996 Maximo Bosch (Chile);
- 1996–1998 Irene Loiseau (Argentina);
- 1998–2000 Nelson Maculan (Brazil);
- 2000–2002 Lorena Pradenas (Chile);
- 2002–2004 Horacio H. Yanasse (Brazil);
- 2004–2006 Sira Allende (Cuba);
- 2006–2010 Héctor Cancela (Uruguay).

The main events organized by ALIO are the biennial CLAIO conferences, which have been hosted at the following cities: 1982—Rio de Janeiro, Brazil; 1984—Buenos Aires, Argentina; 1986—Santiago de Chile, Chile; 1988—Rio de Janeiro, Brazil; 1990—Buenos Aires, Argentina; 1992—Ciudad de México, México; 1994—Santiago de Chile, Chile; 1996—Rio de Janeiro, Brazil; 1998—Buenos Aires, Argentina; 2000—México D.F., México; 2002—Concepción, Chile; 2004—La Habana, Cuba; 2006—Montevideo, Uruguay; 2008—Cartagena de Indias, Colombia. Next CLAIO will be held in Buenos Aires, Argentina, in June 2010, together with a joint ALIO–INFORMS international meeting. The CLAIO series has been extremely important to promote regional and world wide synergy and cooperation between researchers of different countries; a measure of its success is the number of participants, which has grown from 12 persons (in the first conference, in 1982) to more than five hundred in the 2008 conference.

Other conferences coorganized by ALIO include the ALIO–EURO Workshop on Applied Combinatorial Optimization Series. The first workshop took place in 1989 at Rio de Janeiro, Brazil; the second one in 1996 at Valparaiso, Chile, 1996; and the following ones (held triennially, and alternating between a European and a Latin–American location) were held at Erice,

Italy (1999); Pucon, Chile (2002); Paris, France (2005); and Buenos Aires, Argentina (2008). A recent joint undertaking by ALIO, INFORMS, and IFORS was the launching of the biennial ALIO/INFORMS/IFORS Teaching Effectiveness Colloquium Workshop series, which has been held in Montevideo, Uruguay (2006) and Cartagena, Colombia (2008).

Between 1986 and 2000, ALIO published a scholarly journal, *Investigación Operativa*, ISSN 1014-8264. This was a venue for publishing high quality research (written in any Latin language or in English). One of the goals of *Investigación Operativa* was to promote the integration, publication, and dissemination of work in OR conducted within the Latin-Ibero-American community. However, the journal also welcomed original, relevant works coming from any other country. The journal contents were selected so as to maintain equilibrium between theoretical and practical work in OR, in all fields of human activity. The journal editors were Nelson Maculan, Celso Carneiro Ribeiro, and José Mario Martínez. Although academically successful, financial issues made it very difficult to continue operations of the journal; after negotiations with IFORS, in 2000, the journal was merged within IFORS flagship journal, *ITOR*, ISSN 0969-6016. *ITOR*'s current general editor is Celso Carneiro Ribeiro, who has taken advantage of his experience as one of the former editors of *Investigación Operativa* to

lead a very successful improvement process in that journal.

Another noteworthy initiative by ALIO is the ELAVIO series, organized since 1994. The ELAVIOs are the Latin-American Operational Research Summer Schools, whose objective is to bring together the graduate students from all countries in the region and give them the opportunity to assist with the short courses, tutorials, discussion panels, and lectures on advanced topics in OR given by senior researchers and scholars. The full list of the ELAVIOs held include Punta de Tralca, Chile (1994); Mendes, Brazil (1995); Bariloche, Argentina (1996); Montevideo, Uruguay (1997); Viña del Mar, Chile (1998); Mendes, Brazil (1999); Habana, Cuba (2000); Viña del Mar, Chile (2001); Vaquerías, Argentina (2003); Montevideo, Uruguay (2004); Villa de Leyva, Colombia (2005); Itaipava, Brazil (2007); Chosica, Peru (2008); and El Fuerte, Mexico (2009). The ELAVIO schools are organized with the sponsorship of IFORS, which makes it possible to exchange students with EURO and CORS, as well as support participants from developing countries. As part of this same agreement, young scholars from ALIO regularly participate in the EURO Summer Institutes (ESIs).

ALIO maintains a homepage at <http://www.dc.uba.ar/alio>, including information about its member societies, current authorities, organized events, and other items of interest to the OR community.

LEARNING WITH DYNAMIC PROGRAMMING

PETER I. FRAZIER
School of Operations Research
and Information Engineering,
Cornell University, Ithaca,
New York

Frequently in operations research and management science we face uncertainty, whether in the form of uncertain demand for goods, uncertain travel times in networks, or uncertainty about which set of parameters best calibrates a simulation model. Often when facing uncertainty we are also offered the opportunity to collect some information that will mitigate uncertainty's effects. On the one hand, collecting information allows us to make better decisions and produce better outcomes. On the other hand, collecting information carries a cost, whether in time or money spent, or in the opportunity cost sacrificed collecting one piece of information when we could have collected another. How can we optimally balance these costs and benefits?

One way to formulate such problems is with Bayesian methods [1], in which we begin with a *prior* probability distribution that describes our subjective belief about how likely each of the many different possible truths are. Dynamic programming (DP) [2] offers a general way to formulate and solve such Bayesian sequential learning problems. This DP formulation provides value in three ways. First, in some cases, the DP formulation allows computing the optimal solution. This is usually only true for smaller problems (e.g., the inventory problem considered in Ref. 3), because the curse of dimensionality [4] prevents computing the solution to larger problems in a practically feasible amount of time. Second, the DP formulation sometimes allows structural results to be shown theoretically, which either provides intuition about the problem and the behavior of the optimal policy as in, for example, Ding *et al.* [5],

or provides a characterization of the optimal policy that may be directly exploited to find an optimal policy, as in sequential hypothesis testing [6]. Third and finally, the DP formulation sometimes suggests useful heuristics (e.g., knowledge-gradient methods [7]) for complex and large-scale learning problems.

The sequential learning problems that we consider here have been studied in several separate communities. Within the operations research community, sequential learning problems, as well as the way in which DP can be used to confront them, were recognized in early work by Howard [8,9]. Within the resulting literature, surveyed in Refs 10 and 11, such sequential learning problems were called *partially observable Markov decision processes* (POMDP). This work on POMDPs was continued in the artificial intelligence and reinforcement learning communities [12,13], where the emphasis is on general purpose complexity results and algorithmic strategies that apply to the whole spectrum of POMDPs. Specific applications tend to come from robotics, game playing, and other problems that are thought to be exemplars for the problems that humans face when interacting in a general way with their environment. More recently, these problems have also been called *Bayes adaptive Markov decision processes* and optimal learning problems [14,15]. Within statistics, a closely related field is sequential design of experiments [16–18]. Here, the emphasis is on rigorous treatment of a class of problems that tend to appear in laboratory and other experimental settings. This field is also closely related to sequential analysis [19]. While much of the literature is written for a specialized research audience, the tutorial [15] introduces this class of problems in an accessible and comprehensive way for the general operations research (OR) audience.

The problems that we consider here are all *sequential*, by which we mean that data is processed as it is collected, and decisions are made on the basis of all available data. Acting sequentially allows adaptation and provides

the possibility of more efficient action. This is in contrast to nonsequential problems, where decisions are made before observing any data at all. The terms “on-line” and “offline” are sometimes used instead of “sequential” and “nonsequential,” although these terms can also refer to differences in reward structure (see the section titled “Multiarmed Bandits”). Sequential methods require a more sophisticated analysis than nonsequential methods, but often provide much better performance.

We begin by describing in detail one sequential learning problem, the Bernoulli ranking and selection (R&S) problem. This problem is simple enough to be described in detail here and to be solved explicitly using DP, but it also contains essential elements observed in all sequential learning problems. Thus, it serves as an excellent example of this class of problems and the way in which DP can be applied toward their solution. We then expand our scope to describe several other problems from operations research and management science to which DP has been fruitfully applied.

THE RANKING AND SELECTION PROBLEM

In this section, we describe an important learning problem in detail, and show how DP may be used to solve it. This problem is the R&S problem, which has a long history beginning with the work of Bechhofer [20,21]. Historically, this problem was most often considered in a non-Bayesian framework (see Ref. 22 for a review), but the Bayesian formulation has grown more prominent in recent decades (see Ref. 23 for a review).

In the R&S problem, we consider the efficient use of experimentation (either simulation based or physical) to determine which of several “alternatives” is best. As an example, suppose that we have several different inventory policies, and we would like to use computer simulation to determine which of these has the highest average profit. We are limited in the number of simulations we can perform by the amount of simulation time that we have available, and we would like to allocate this time to simulations of the different inventory policies. This allocation should

maximize our ability to determine which of the inventory policies is best.

One approach is to run a few simulations of each alternative to roughly estimate which alternatives are likely to be among the best, and then concentrate most of our later simulation effort on just these alternatives. When done intelligently, this allows us to find the best alternative with fewer samples than we could have by spreading our simulation budget equally across the alternatives. The essential question in R&S is how this allocation may be done as efficiently as possible. DP offers an answer.

We formulate the R&S problem formally by supposing that we have a limited budget N of samples to be allocated among k alternatives, and a sampling distribution is associated with each alternative. The R&S literature often assumes that this sampling distribution is normal, but it will be easier to illustrate this problem if we assume that the sampling distribution is Bernoulli. Let θ_x be the parameter of the Bernoulli distribution for alternative x , so θ_x is the probability of observing a “success” from alternative x . This quantity θ_x is unknown, but we will be able to learn it through sampling. Our goal is to use sampling to find the alternative with the largest θ_x .

Time is indexed by n , from $n = 1$ up to $n = N$. At each time $n \leq N$, we choose an alternative $x_n \in \{1, \dots, k\}$ to sample from among the full set of k alternatives. This choice may depend upon all previously observed samples, $(x_m, y_m)_{m < n}$, where x_1 is chosen deterministically. We then observe a sample y_n whose distribution is

$$y_n \mid \theta, x_n \sim \text{Bernoulli}(\theta_{x_n}).$$

This sample is conditionally independent of all other x_m and y_m , $m < n$, given θ and x_n . At the final time N , we select an alternative x_* , and we receive a terminal reward θ_{x_*} . This is the reward that we receive when we implement the alternative x_* in the real world. The decision x_* may depend upon all previously observed samples, $(x_m, y_m)_{m \leq N}$. Given perfect information, we would choose x_* to be equal to $\arg \max_x \theta_x$, but this information is unavailable. Instead, we must base our choice of

x_* upon the sampling information acquired. The crux of the R&S problem is choosing the sampling decisions $x_1, \dots, x_N$ in order to best support our final implementation choice x_* .

Formally, we define a policy π to be a collection of random variables $(x_n)_{1 \leq n \leq N}$ and x_* . We define F_n to be the sigma-algebra generated by the random variables x_m, y_m , $m \leq n$. We enforce the way in which decisions may depend upon previous observations by requiring that $x_n \in \mathcal{F}_n - 1$ for $n \geq 1$ and $x_* \in \mathcal{F}_N$. We define Π to be the set of all such policies π .

Momentarily fixing θ , the expected reward obtained by a policy π is

$$\mathbb{E}^\pi [\theta_{x_*} | \theta], \quad (1)$$

where $\mathbb{E}^\pi$ indicates the expectation taken with respect to policy π . When an expectation depends upon the policy, we write $\mathbb{E}^\pi$, and when it does not we simply write $\mathbb{E}$. Although the only decision that appears in this expression is x_* , the information upon which x_* is based depends critically upon the sampling decisions x_n . Indeed, we will see that choosing x_* given the available information is relatively straightforward, and the difficulty in the R&S problem is choosing x_n , $n \leq N$, i.e., choosing which information to collect.

We would like to choose the policy π that maximizes this quantity (Eq. (1)). The difficulty is that Equation (1) depends upon θ , which is unknown. If we knew θ , we could simply choose $x_* \in \arg \max_x \theta_x$ without sampling at all. Furthermore, different policies may be better for different values of θ . We need to combine the criteria (Eq. (1)) across multiple values of θ and find a policy π that does well according to this combined criterion. One method for combining Equation (1) across multiple values of θ is the Bayesian method. In this method, we suppose that we have a prior probability measure $\mathbb{P}_0$ on θ , and that we wish to maximize the expected reward received when θ is drawn at random according to $\mathbb{P}_0$. This expected reward is $\mathbb{E}[\mathbb{E}^\pi [\theta_{x_*} | \theta] | \theta \sim \mathbb{P}_0] = \mathbb{E}^\pi [\theta_{x_*}]$, and our goal in Bayesian R&S is to find a policy π that solves

$$\sup_{\pi \in \Pi} \mathbb{E}^\pi [\theta_{x_*}]. \quad (2)$$

The prior probability measure $\mathbb{P}_0$ may be interpreted in several ways. One may think of it as expressing our subjective belief about the relative importance of various possible configurations. This first interpretation is the one most commonly understood in Bayesian statistics. Secondly, the prior may be interpreted literally in certain limited cases where θ really has been drawn at random from a known probability distribution. This is the case when one is solving R&S problems on a repeated basis, as one might, for example, when calibrating a single simulation model each day to a new set of data. Third and finally, one may interpret the objective function $\mathbb{E}^\pi [\theta_{x_*}] = \int_{\mathbb{R}^k} \mathbb{E}^\pi [\theta_{x_*} | \theta] \mathbb{P}_0(d\theta)$ as a linear combination of the individual objectives $(\mathbb{E}^\pi [\theta_{x_*} | \theta])_{\theta \in \mathbb{R}^k}$, just as we often treat multi-objective optimization problems by optimizing a linear combination of the objectives. In this interpretation, the choice of $\mathbb{P}_0$ is simply the choice of which linear combination to optimize.

Given a prior distribution $\mathbb{P}_0$ and the information collected up to a time n , we have a posterior distribution $\mathbb{P}_n$. In particular, given a sequence of measurements $x_{1:n} = x_1, \dots, x_n$ and observations $y_{1:n} = y_1, \dots, y_n$, the posterior $\mathbb{P}_n$ is defined as the measure on $\mathbb{R}^k$, $\mathbb{P}_n\{\theta \in du\} = \mathbb{P}_0\{\theta \in du | x_{1:n}, y_{1:n}\}$. We write $\mathbb{E}_n$ to indicate the expectation taken with respect to this posterior distribution. In general, the posterior may be calculated using Bayes' rule,

$$\mathbb{P}_n\{\theta \in du\} \propto \mathbb{P}\{y_{1:n} | x_{1:n}, \theta = u\} \mathbb{P}_0\{\theta \in du\}. \quad (3)$$

We assume that the decisions x_n depend only upon the posterior. One can show that the supremum (Eq. (2)) is unchanged if Π is restricted to this class of policies.

To facilitate computation of the posterior, it is convenient to suppose that the prior has a certain parametric form. If θ_x has a $\beta(a_{0x}, b_{0x})$ distribution under the prior $\mathbb{P}_0$ and is independent of all θ_j , $j \neq x$, then a calculation beginning with Equation (3) shows that θ_x is also beta-distributed under the posterior $\mathbb{P}_n$, and it remains independent of other θ_j . In particular, $\theta_x \sim \beta(a_{nx}, b_{nx})$, where $a_{nx} = a_{0x} + \sum_{m \leq n} 1_{\{x_m = x\}}(1 - y_m)$ is the sum of a_{0x} and the number of

failures seen from alternative x , and $b_{nx} = b_{0x} + \sum_{m \leq n} 1_{\{x_m = x\}} y_m$ is the sum of b_{0x} and the number of successes seen from alternative x . We define

$$\mu_{nx} = \mathbb{E}_n[\theta_x] = b_{nx}/(a_{nx} + b_{nx})$$

to be the expectation of θ_x under the posterior at time n . The explicit expression $b_{nx}/(a_{nx} + b_{nx})$ follows from a standard computation of the expectation of a beta-distributed random variable [24].

Given this beta prior and its associated beta posteriors, we can simplify the objective function $\mathbb{E}^\pi[\theta_{x_*}]$. Using the tower property of conditional expectation and the $\mathcal{F}_N$ -measurability of x_* , we write $\mathbb{E}^\pi[\theta_{x_*}] = \mathbb{E}^\pi[\mathbb{E}_N^\pi[\theta_{x_*}]] = \mathbb{E}^\pi[\mu_{Nx_*}]$. Thus, the stochastic control problem (2) may be rewritten

$$\sup_{\pi \in \Pi} \mathbb{E}^\pi[\theta_{x_*}] = \sup_{\pi \in \Pi} \mathbb{E}^\pi[\mu_{Nx_*}].$$

This problem can be solved using DP. Because $\mu_{Nx} = b_{Nx}/(a_{Nx} + b_{Nx})$ is a function of a_N and b_N , and because $(n, a_n, b_n)_n$ is a Markov process (we see this below in greater detail), the state of the DP may be taken to be (n, a_n, b_n) . We thus define a value function parameterized by n, a_n , and b_n

$$V(n, a_n, b_n) = \sup_{\pi} \mathbb{E}^\pi[\mu_{Nx_*} | a_n, b_n]. \quad (4)$$

At the final time $n = N$, the only decision left to make is x_* . This decision may depend upon all the information available at this time, and, in particular, it may depend upon μ_{Nx} , $x = 1, \dots, k$. Thus, the optimal x_* is any satisfying $x_* \in \arg\max_x \mu_{Nx}$, and the value function at the final time is

$$V(N, a_N, b_N) = \max_x \mu_{Nx}. \quad (5)$$

Given this final value function, we may compute the value function at earlier times $n < N$ using Bellman's recursion,

$$\begin{aligned} V(n, a_n, b_n) &= \max_x \mathbb{E}[V(n+1, a_{n+1}, b_{n+1}) | x_{n+1} \\ &= x, a_n, b_n] \quad \text{for } n < N. \end{aligned} \quad (6)$$

To write this expectation explicitly, we must consider the distribution of a_{n+1} and b_{n+1} given $x_n = x$, a_n , and b_n . If we measure alternative x and observe a success ($y_{n+1} = 1$), then we increment b_{nx} . Instead, if we observe a failure ($y_{n+1} = 0$), then we increment a_{nx} . Thus, letting e_x be the vector of 0s with a single 1 at component x ,

$$\begin{aligned} b_{n+1} &= b_n + y_{n+1}e_x, & a_{n+1} &= a_n \\ & & & + (1 - y_{n+1})e_x, \end{aligned}$$

and the distribution of a_{n+1} and b_{n+1} is determined by the probability of success, $\mathbb{P}_n y_{n+1} = 1$. Given θ_x , we have $y_{n+1} = 1$ with probability θ_x , but θ_x is unknown. We do have a posterior distribution on θ_x , however, which allows us to write

$$\begin{aligned} \mathbb{P}_n \mathbb{E}\{y_{n+1} = 1\} &= \mathbb{E}_n[y_{n+1}] = \mathbb{E}_n[\mathbb{E}_n[y_{n+1} | \theta]] \\ &= \mathbb{E}_n[\theta_{x_{n+1}}] = \mu_{nx_{n+1}}. \end{aligned}$$

We then immediately have the following expression for the distribution of a_{n+1} , b_{n+1}

$$\begin{aligned} \mathbb{P}_n\{b_{n+1} &= b_n + e_x, a_{n+1} = a_n | x_{n+1} = x\} \\ &= \mathbb{P}_n\{y_{n+1} = 1 | x_{n+1} = x\} = \mu_{nx} \\ \mathbb{P}_n\{a_{n+1} &= a_n + e_x, b_{n+1} = b_n | x_{n+1} = x\} \\ &= \mathbb{P}_n\{y_{n+1} = 0 | x_{n+1} = x\} = 1 - \mu_{nx}. \end{aligned}$$

Thus, $(n, a_n, b_n)_{0 \leq n \leq N}$ is a Markov process whose distribution is determined by the measurement policy π . Note that we do not need to include θ into this stochastic process in order for its dynamics to be well defined. This fact is mathematically quite natural but may seem counterintuitive. The Bayesian assumption of a prior on θ has allowed us to define the way in which our posterior belief on θ changes with measurements, without the need to know θ . This is what allows us to formulate the problem as a DP.

Given the conditional distribution of a_{n+1} , b_{n+1} , we can simplify Bellman's recursion

(6) to

$$\begin{aligned}
 & V(n, a_n, b_n) \\
 &= \max_x V(n+1, a_n + e_x, b_n)(1 - \mu_{nx}) \\
 &\quad + V(n+1, a_n, b_n + e_x)\mu_{nx}, \quad \text{for } n < N.
 \end{aligned} \tag{7}$$

Using the terminal condition (5) and Bellman's recursion (7), one can calculate the value function for all possible states n, a_n , and b_n . There are finitely many such states since $a_n - a_0$ and $b_n - b_0$ have nonnegative integer components whose sum must equal n . The value function for $n = 0$ and $a_{0x} = b_{0x} = 1$ for all x is pictured in Fig. 1 for problems with various values of k and N .

Given the value function as computed in this manner, we may compute an optimal policy as one that chooses its decisions to achieve the maximum in Equation (7). That is, an optimal policy π^* is defined by

$$\begin{aligned}
 x_n \in \arg \max_x & V(n+1, a_n + e_x, b_n)(1 - \mu_{nx}) \\
 & + V(n+1, a_n, b_n + e_x)\mu_{nx}.
 \end{aligned}$$

Although computing the value function using Bellman's recursion is straightforward in theory, it is quite difficult practically when the number of states is very large. In our problem, the number of states can be

reduced by removing n from the state, since it is determined by summing the components of a_n and b_n . It can be further reduced by noting the invariance of the value function to permutations of the alternatives. Even with both space-reducing methods, however, the number of states is very large for even moderate values of k and N . This is the so-called "curse of dimensionality," and presents a great challenge to computation. Several approximation techniques have been proposed for addressing this difficulty [4], but the curse of dimensionality still presents a fundamental challenge to DP.

Despite the challenge presented by the curse of dimensionality, the DP solution to the Bernoulli R&S problem provides a number of benefits. First, it provides explicit solutions for small and moderately sized problems. Second, it provides a testing ground on which heuristic algorithms for larger problems may be benchmarked against optimal solutions. Third, it provides a solid theoretical understanding of the problem that may be extended to provide a number of insights into the nature of the problem and the behavior of the value function and associated optimal solution and (see Ref. 25 for similar insights in a sequential normal R&S problem). Software for computing several of the leading algorithms for Bayesian R&S of normal populations is available in the InfoCollection library at 26.

Figure 1. Value function at $n = 0$, with $a_{0x} = b_{0x} = 1$ for Bernoulli R&S as a function of the number of alternatives (k) and the measurement budget (N).

FURTHER APPLICATIONS

In the previous section, we saw how DP can be used to solve one particular sequential learning problem, the fully sequential Bernoulli R&S problem. This DP approach can be applied to nearly any learning problem in which there is some unknown truth (θ in the R&S problem) about which we are learning through our actions while simultaneously collecting rewards whose distribution depends on our actions and the truth. To formulate such problems as DPs, we create a state space consisting of the space of posterior beliefs, and the value function is defined using Bellman's recursion and the predictive distribution for the observation that follows from the current posterior distribution.

In this section, we briefly describe other problems from the literature in which the DP formulation has been useful. In some of these problems, the DP has been solved explicitly. In others, the DP has suggested useful heuristics or provided insights into the structure of the problem. In addition to the problems detailed below, many other sequential learning problems have been approached using DP. These include sequential change detection [27,28], dynamic pricing [29], medical diagnosis [30], and many others (see Ref. 7 Section 1.1 for a list).

Multiarmed Bandits

The multiarmed bandit problem is similar to the R&S problem, except that we receive each y_n as a *reward* rather than merely as an observation. The goal is to maximize the expected discounted total reward received over time

$$\sup_{\pi \in \Pi} \mathbb{E}^\pi \left[\sum_{n=1}^N \gamma^{n-1} y_n \right],$$

where $\gamma \leq 1$ is a discount factor and $N \leq \infty$.

The name “multiarmed bandit” originates in a colorful example in which each alternative represents one arm of a multiarmed slot-machine (slot machines are sometimes called “one-armed bandits”). Pulling arm $x_n \in 1, \dots, k$ results in a payoff whose distribution is fixed but unknown. These distributions can only be learned through experimentation. The goal in this problem is to maximize the expected total value of our earnings over time.

This playful example is a surrogate for a large number of problems in many different fields in which the only way to learn the quality of some action is to actually perform it in the real-world and suffer its corresponding real loss or reward. The optimal behavior in such problems is necessarily different and more cautious than that in R&S, in which one has an experimental test bed available and which does not suffer extreme consequences for testing poor alternatives. This difference in behavior due to the reward structure is sometimes discussed by calling the reward

structures similar to R&S “offline,” and calling those similar to multiarmed bandits “online.” This difference should not be conflated with the difference discussed in the introduction between sequential policies, which make their decisions x_n based upon all of the available data, and nonsequential policies, which make their decisions before seeing any data.

The multiarmed bandit problem can be solved using DP if we assume rewards are conditionally independent given the alternative measured, and if we take the infinite horizon discounted case ($\gamma < 1$ and $N = \infty$). This solution is known as the *Gittins index policy*, and was introduced in Ref. 31. This policy is derived by considering a number of smaller problems, one for each alternative. In each smaller problem, we may pull only a single arm x , and we decide adaptively when to stop. Upon stopping, we are given a fixed retirement reward M . This can be modeled by requiring the policy to satisfy $x_n \in 0, x$ for all n , and defining $\tau = \inf n \geq 0 : x_n = 0$ as the time at which the policy decides to retire. Let Π_x be the space of all such policies. The smaller problem then has a value function V parameterized by the arm x being pulled and the retirement reward M

$$V(P; M, x) = \sup_{\pi \in \Pi_x} \mathbb{E}_n^\pi \left[\sum_{n=1}^{\tau-1} \gamma^{n-1} y_n + \gamma^{\tau-1} M \mid \mathbb{P}_0 = P \right],$$

where P is a probability distribution on the sampling distribution from arm x . In many important cases, it can be parameterized with a few (often one or two) real numbers. We then define a *Gittins index*, $m(P, x)$, to be the smallest retirement reward M such that the optimal policy restricted to pull arm x retires immediately. This is written as

$$m(P, x) = \inf \{ M : V(P; M, x) = M \}.$$

One can then show using DP that the optimal policy for the original multiarmed problem is to pull the arm with the largest Gittins index. One can refer to the original proof in Ref. 31, but more accessible and equally

rigorous proofs may be found in Refs 32 or 33. The resulting optimal policy is

$$x_n \in \arg \max_x m(\mathbb{P}_n, x).$$

To use this optimal policy, we must be able to compute $m(\mathbb{P}_n, x)$, which requires solving and calculating value functions for the smaller problems. This is possible because the state space of this smaller problem is *much* smaller than that for the full multiarmed bandit problem, consisting only of the posterior distribution on a single alternative. In many cases, including Bernoulli rewards with a beta prior on the probability of reward, and normal rewards with known variance and a normal prior on the sampling mean, this state space has only two dimensions. Such small dynamic programs can be solved numerically using standard techniques. Tables of Gittins indices for the beta-Bernoulli and normal-normal cases can be found in Ref. 34, and an easy-to-use analytic approximation for the normal case may be found in Ref. 35. This is in contrast to the full problem under these priors, whose state space has $2k$ dimensions. Computation scales exponentially in the dimension, which makes the smaller problem eminently solvable, while a brute-force numerical solution of the full problem is intractable.

If we relax the assumptions of the Gittins index policy, for example, by taking a finite horizon or correlated y_n , then no tractable optimal solution is known. The proof of the Gittins index policy relies on a decomposition of the problem into single-arm subproblems, which is quite fragile to such changes in assumptions. To solve the problem optimally, one must solve the full DP, which is computationally intractable because of its large state space. Although the optimal policy is unknown, knowledge of the underlying DP formulation and the Gittins index policy has supported the creation and analysis of a number of heuristics. Many of these heuristics are index-based solutions that are not optimal, but have pleasing empirical and theoretical properties. See, for example, heuristics for restless bandit problems [36] and other variants discussed in Section 3

of Ref. 37. DP-motivated heuristics for bandits with finite-horizons and/or correlated rewards are discussed in Refs 38 and 39.

For complete treatments of the classic Bayesian bandit results, see Refs 16,18, or 37. See also the surveys [40] from the economics literature, [41] from the computer science literature, or Chapter 10 of Ref. 4 from the operations research literature. Literature on non-Bayesian formulations of the multiarmed bandit problem in which worst-case regret is minimized is also available. For an introduction, see Chapter 6 of Ref. 42.

Bayesian Global Optimization

Suppose that we have a continuous function f that we would like to optimize over some compact domain $\mathcal{X} \subset \mathbb{R}^d$. The only access to the function is through a black box that tells us the function's value f at points x_n of our choosing, but possibly obscured by noise. We suppose that we have no access to derivative or other information. We further suppose that function evaluation takes a long time (minutes or hours), and so we wish to minimize the number of function evaluations we perform in order to find a "good" solution. Such problems occur quite frequently, for example, when optimizing a complex simulation model, or optimizing temperature and pressure in an industrial chemical-manufacturing process. Time-consuming function evaluation differentiates the problem from other derivative-free global optimization problems for which the goal may be to minimize algorithmic computation time rather than the number of function evaluations, for which algorithms requiring less computation may be desirable.

We may formally pose the problem of finding an algorithm that finds as good a solution as possible in a bounded number of function evaluations as a Bayesian learning problem. This formulation shares substantially with the aforementioned ranking and selection problem, with the critical difference being that we are now searching on a continuous domain for the best point rather than among a finite set of alternatives.

As in the R&S problem, we begin with a prior distribution on the truth, but here the prior is on the function f . Despite the large and complex nature of the space of all

possible continuous functions on a compact domain, the class of Gaussian process priors forms an analytically convenient class of prior distributions on this space. They have been successfully applied to problems in spatial statistics [43] and machine learning [44]. A Gaussian process prior is parameterized by its mean function $\mu : \mathbb{R}^d \mapsto \mathbb{R}$ and its covariance function $\Sigma : \mathbb{R}^d \times \mathbb{R}^d \mapsto \mathbb{R}$ (Σ is required to be a positive semidefinite function), and may be written $f \sim \text{GP}(\mu, \Sigma)$. With this prior, the problem is stated as

$$\sup_{\pi} \mathbb{E}^{\pi} [f(x_*)], \quad (8)$$

where as in R&S x_* is chosen as well as possible based on the measurements (x_n, y_n) , $n = 1, \dots, N$.

The DP formulation of this problem then proceeds as it did in the R&S problem, but we now have a posterior on the space of functions. One finite-dimensional parameterization of this posterior is simply the set of points and functions evaluations observed so far $(x_m, y_m)_{m \leq n}$. The state space is then quite large, being continuous with a number of dimensions that grows with N . One may also discretize the domain into k points and work with the posterior only on these points. The state space then may be chosen to have a fixed size, but its dimension is still on the order of k^2 . Under either parameterization, the high-dimensionality of the state space prevents computation in all but the simplest cases.

Despite the difficulty in solving the DP, several heuristics that work well empirically may be understood as DP-based approximations to the optimal policy. One such heuristic is the knowledge-gradient (KG) method, which defines

$$\text{KG}_n(x) = \mathbb{E}_n \left[\sup_{x' \in \mathcal{X}} \mu_{n+1}(x') \mid x_{n+1} = x \right],$$

where $\mu_{n+1}(x') = \mathbb{E}_{n+1} f(x')$. The KG method then selects $x_n \in \arg \max_x \text{KG}_n(x)$ as the next point to measure. This is the decision that would be optimal under the DP if we had only a single measurement left to make, that is, if $n = N - 1$. In this sense, the KG method is a one-step, lookahead policy. In

general, computing the KG policy is a difficult computational problem. One approach is to discretize the domain, as in Ref. 45. For truly continuous problems, discretization is an approximation, while for problems with naturally integral decision variables interpolated by a continuous mean function, for example, choosing the reorder point for an inventory policy, this is a natural modification of the BGO problem.

Another heuristic is the expected improvement (EI) method, which is most commonly formulated in the noise-free case. Although this method is often presented without describing the underlying stochastic optimization problem (8) and its DP framework, it can be understood as being motivated by the DP. We consider the noise-free case and restrict our implementation decision to be from among those points that we have already measured. To obtain the policy that is now optimal with one measurement remaining under this restriction, we must replace the supremum over the whole domain $\mathcal{X}$ in the definition of $\text{KG}(x)$ by a maximum over only the points we have measured, $\{x_m : m \leq n + 1\}$. This maximum may be written $\max(f(x_m) : m \leq n + 1) = \max(y_{n+1}, f_n^*)$, where we have used that $\mu_{n+1}(x_m) = f(x_m) = y_m$ for $m \leq n + 1$ in the noise-free case, and then defined $f_n^* = \max_{m \leq n} f(x_m)$ to be the value of the best point observed so far. Subtracting f_n^* , which does not depend on x_{n+1} , provides the expected improvement function

$$\text{EI}(x) = \mathbb{E}_n [(y_{n+1} - f_n^*)^+ \mid x_{n+1} = x].$$

The EI method then recommends that we sample the alternative with the largest $\text{EI}(x)$. This method was introduced in Refs 46–48, building on previous work [49–51]. It was modified to allow measurements with stochastic noise in Ref. 52, and to numerical noise in Ref. 53. For a complete general introduction, see Ref. 54, or for a brief overview see Section 6.3 of Ref. 55.

Thus, both KG and EI methods may be seen as being motivated by the DP. Both are one-step lookahead policies, but under different assumptions on the set of allowed implementation decisions. The KG method

is more difficult to compute, but generalizes more naturally to noisy measurements, and was shown to perform better than EI-based methods in an empirical study [45].

A number of software packages have been written that can calculate Bayesian estimates of the function f using Gaussian process priors. One such software package is DACE (Design and Analysis of Computer Experiments) [56,57]. An up-to-date collection of other software packages is maintained at the website [58], which also lists texts, articles, and other websites relevant to estimation with Gaussian processes.

Software packages for calculating the measurement decisions of DP-based optimization policies are also available. Publicly available code associated with Forrester *et al.* [54] implement a number of prediction methods and sampling algorithms. The SPACE software package [59] implements the efficient global optimization (EGO) algorithm [48] for noise-free optimization, and the commercial software package TOMLAB includes an implementation of the sequential kriging optimization (SKO) algorithm of Ref. 52 for the noisy measurement case. An implementation of the KG algorithm [45] for discretized spaces is available in the MatlabKG package [26].

Sequential Hypothesis Testing

In the sequential hypothesis testing problem, we learn which of the two hypotheses is correct by observing a sequence of samples $y_1, y_2, \dots$. Under one hypothesis, the samples are coming from a density f_0 , and under the other hypothesis they are coming from a different density f_1 . Let $\theta \in \{0, 1\}$ be the correct hypothesis, so f_θ is the true sampling density. We pay a cost c for each sample observed and we may stop observing samples at any time. Let τ be the number of samples observed, and we require that it be a stopping time of the filtration generated by $y_1, y_2, \dots$. Upon stopping, we choose a hypothesis x_* and suffer a loss that is 0 if $\theta = x_*$ and equal to d_θ otherwise. In the Bayesian version of the problem, we begin with a prior probability that $\theta = 1$, and we seek a stopping time τ that minimizes the expected loss $\mathbb{E}[c\tau + d_\theta \mathbb{1}_{\theta \neq x_*}]$.

This problem was introduced and solved in Ref. 6, where the solution was shown to be of the form

$$\tau = \inf \{t \geq 0 : L_t \notin [A, B]\},$$

$$x_* = \mathbb{1}_{\{L_t \geq 0\}},$$

for some levels A and B , where $L_t = \sum_{s \leq t} \log(f_1(y_s)) - \log(f_0(y_s))$ is the log-likelihood at time t . A policy of this form is called a *sequential probability ratio test* (SPRT).

Wald *et al.* [6] show that the SPRT is also optimal in another, non-Bayesian, sense. For any given $\alpha_0 \in (0, 1)$ and $\alpha_1 \in (0, 1)$, the expected number of samples under both hypotheses, $\mathbb{E}[\tau | \theta = 0]$ and $\mathbb{E}[\tau | \theta = 1]$, is minimal among all policies satisfying $\mathbb{P}^\theta x_* \neq \theta | \theta = 0 \leq \alpha_0$ and $\mathbb{P}^\theta x_* \neq \theta | \theta = 1 \leq \alpha_1$. This form of optimality is surprisingly strong because it simultaneously minimizes the expected number of samples taken under both hypotheses. It is known as *Neyman–Pearson optimality* because of its similarity to Neyman–Pearson optimality for nonsequential statistical tests [60]. A modern and accessible treatment of the results of Ref. 6 may be found in Ref. 61. Also see Ref. 62 for a detailed survey of this and many related problems is sequential analysis.

The original motivation for this problem was in reducing the number of rounds of ammunition required to test antiaircraft guns and ordnance during World War II [63], but it or problems similar to it appear whenever we wish to take samples in order to make a decision. One class of similar problems of particular importance appear in the design of clinical trials [64].

Inventory Control

In the classic newsvendor problem [65], we have daily demand for a perishable product, for example, newspapers, and we wish to maximize our expected revenue. Each day we choose a number of units x_n of inventory to buy at a per-unit cost c , and we sell units at a per-unit price of p until we either run out of inventory or meet the days' demand D_n .

If the demand distribution is known, then the classic analysis easily characterizes

the optimal solution. In many problems, however, we do not know the true demand distribution but are instead learning it from sales data. This is particularly true with a new product, or with a product for which the demand distribution is changing over time. When the demand distribution is unknown but fixed, the Bayesian version of this problem may be written

$$\sup_{\pi} \mathbb{E}^{\pi} \left[\sum_{n=0}^N -cx_n + p \min(D_n, x_n) \right]$$

where the demand distribution F is unknown and $D_n|F$ come independently and identically distributed from F . This problem may be solved using DP, where the state of the DP is a parameterization of the posterior belief on F at the current time.

If we observe all of the demand, even if we are unable to meet it, then the DP simplifies and the optimal stocking decision is the same as the greedy stocking decision, $\arg\max_x \mathbb{E}_n[-cx_n + p \min(D_n, x_n)]$. Instead, if observation of demand is censored when we stock out of product, as it often is in practice, then the solution to the DP is more complicated. Ding *et al.* [5] use the DP formulation to show that the optimal policy in the presence of censoring orders at least as much as the greedy policy, and possibly more. An easily computed solution is provided in Ref. 3 for cases with either exponential demand with unknown rate, or Weibull demand with known shape but unknown mean. In these cases, a DP with a two-dimensional state space may be solved using a one-dimensional calculation.

CONCLUSION

We have shown how DP can be used to analyze a number of different learning problems from operations research and management science: ranking and selection, multiarmed bandits, global optimization, sequential hypothesis testing, and inventory control. These are just a few of the interesting and important problems in sequential learning that can be approached

using DP. In some cases, the DP formulation provides an explicit solution, while in others it provides useful heuristics and insight into the problem and the behavior of the optimal policy. Many other important problems remain that we believe can be profitably approached with DP, and we hope that this article inspires readers to apply DP methods to these problems in the future.

LEVEL-DEPENDENT QUASI-BIRTH-AND-DEATH PROCESSES

JEFFREY P. KHAROUFEH

Department of Industrial Engineering,
University of Pittsburgh, Pittsburgh,
Pennsylvania

INTRODUCTION

A quasi-birth-and-death (QBD) process is a bivariate Markov process with state space $S = \{(i, j) : i \geq 0, j = 1, 2, \dots, m\}$ where i is called the *level* of the process, j is called the *phase* of the process, and m is an integer that can be finite or infinite. The process is restricted in level jumps only to its nearest neighbors but is unrestricted in the phase dimension. More precisely, from state $(i, j) \in S$ the process may transition to states of the form (i, k) , $(i - 1, k)$ or $(i + 1, k)$, but not to states of the form $(i \pm n, k)$ where $n \geq 2$. Clearly, the QBD process is an extension of the standard birth-and-death process whose state space consists only of the level i . When the transitions of a QBD process are independent of the level, it is termed a *homogeneous* or *level-independent* QBD process. Otherwise, it is termed an *inhomogeneous* or *level-dependent* quasi-birth-and-death (LDQBD) process. This very general class of models finds wide applicability in the modeling of queueing systems, particularly those with complex arrival and/or service processes such as the $PH/M/\infty$ queue. Several queueing, and non-queueing, applications of LDQBD processes will be discussed in the final section titled "Further Reading and Applications." The level-independent version has been studied extensively by a number of researchers and is given a very lucid treatment in the excellent text by Latouche and Ramaswami [1]. As a prototypical example, the homogeneous QBD process can be used to model

the $M/M/1$ queueing system in a random environment where the level i corresponds to the number of customers in the system, and the phase j is the state of an exogenous environment process that governs the arrival and/or service rates [2]. The class of QBD models, and their associated matrix-analytic solution techniques, provide a powerful set of tools for analyzing a wide variety of stochastic models arising in queueing theory, computer and communications systems, reliability modeling and analysis, inventory systems, and many others. For further information on the homogeneous QBD process, please see ***Level-Independent Quasi-Birth-and-Death Processes***.

The main purpose of the present article is to formally define and describe LDQBD processes whose transitions depend explicitly on the level i . Although their structure, and many of their attributes, mirror those of the level-independent version, their analysis and computational aspects are significantly more complicated. Here, we review both discrete- and continuous-time versions of the LDQBD process. For each type, we discuss necessary and sufficient conditions to establish positive recurrence, describe the limiting distribution, and discuss computational methods proposed for analyzing these models. We begin by describing the discrete-time version in the next section.

DISCRETE-TIME LDQBD PROCESSES

Suppose $\{(X_n, J_n) : n \geq 0\}$ is a discrete-time Markov process on the state space $S = \{(i, j) : i \geq 0, j = 1, 2, \dots, m\}$ where i and j are the level and phase of the process, respectively. For the purposes of this article, we will assume m is finite; however, m may be infinite and/or depend explicitly on the level i (as described by Bright and Taylor [3]). For the sake of notational brevity, let $\{Z_n : n \geq 0\} \equiv \{(X_n, J_n) : n \geq 0\}$. The one-step transition probability matrix of this process possesses the typical block tridiagonal form of a QBD process and is given by

$$P = \begin{bmatrix} A_1^{(0)} & A_0^{(0)} & 0 & 0 & \cdots \\ A_2^{(1)} & A_1^{(1)} & A_0^{(1)} & 0 & \cdots \\ 0 & A_2^{(2)} & A_1^{(2)} & A_0^{(2)} & \cdots \\ 0 & 0 & A_2^{(3)} & A_1^{(3)} & \cdots \\ \vdots & \vdots & \vdots & \vdots & \ddots \end{bmatrix}. \quad (1)$$

For $i \geq 0$ and $\ell = 0, 1, 2$, $A_\ell^{(i)}$ are m -order non-negative matrices, and the row sums are equal to unity, that is, the row sums of $A^{(i)} \equiv A_2^{(i)} + A_1^{(i)} + A_0^{(i)}$ and $A_1^{(0)} + A_0^{(0)}$ are equal to 1. To interpret the entries of P , we note that for $i \geq 1$, the process transitions from (i, j) to $(i-1, k)$ with probability $[A_2^{(i)}]_{j,k}$, or it transitions to state $(i+1, k)$ with probability $[A_0^{(i)}]_{j,k}$. A transition from (i, j) to (i, k) occurs with probability $[A_1^{(i)}]_{j,k}$. Finally, when $i = 0$, from state $(0, j)$ the process transitions to state $(1, k)$ with probability $[A_0^{(0)}]_{j,k}$, or to state $(0, k)$ with probability $[A_1^{(0)}]_{j,k}$. It should be clear that the rows of P are blocks of order m , and the structure indicates that the process is skip-free in the level in both directions. For the remainder of this section, we assume that P is irreducible.

Positive Recurrence and Limiting Distribution

A natural question is whether the Markov process with transition matrix P of Equation (1) possesses a limiting distribution, and if so, under what conditions does the distribution exist and what is its form? Unfortunately, the extreme generality of the LDQBD process precludes the development of generic tools that can be used to establish such properties as irreducibility, recurrence, and positive recurrence; however, in practice, it is often possible to establish these properties for specific applications using the attributes of the model. Stochastic dominance arguments are also often employed to show that the LDQBD process is stochastically dominated by a simpler process (e.g., a homogeneous QBD process) whose irreducibility and recurrence properties can be more easily established. Our aim here is to review the theoretical conditions for positive recurrence of irreducible LDQBD processes.

Denote the limiting distribution of $\{Z_n : n \geq 0\}$ by a positive row vector π that uniquely solves the system $\pi P = \pi$ and

$\pi e = 1$, where e is a column vector of ones. The vector π is partitioned by levels into subvectors so that

$$\pi = (\pi_0, \pi_1, \pi_2, \dots),$$

and π_i contains the limiting probabilities for states in level i , that is, the states in the set $L_i \equiv \{(i, 1), (i, 2), \dots, (i, m)\}$. Note that π_i has m components for each i . As shown in Chapter 6 of Ref. 1, the vector π_i assumes a *matrix-geometric* form when the process is level-independent, that is, when for $\ell = 0, 1, 2$, $A_\ell^{(i)} = A_\ell$ for every $i \geq 0$. More specifically, for $i \geq 0$, the vector π_i satisfies

$$\pi_i = \pi_0 R^i,$$

where R is a fixed matrix (independent of the level) such that for any pair of phases j and k , $[R]_{j,k}$ is the expected number of visits to state $(1, k)$ before returning to the set L_0 , provided that the process starts in state $(0, j)$. The result is a matrix analog to the scalar geometric distribution. (For a more thorough treatment of the matrix-geometric distribution, please see **Matrix-Geometric Distributions**.) Before stating the necessary and sufficient conditions for positive recurrence of a LDQBD process, we first assume it is irreducible, aperiodic, and positive recurrent in order to characterize the limiting distribution π . The following theorem mirrors Theorem 12.1.1. in Ref. 1 and is stated here without proof.

Theorem 1. *If the LDQBD process with transition probability matrix given by Equation (1) is irreducible, aperiodic, and positive recurrent, then there exist matrices $\{R_i : i \geq 1\}$, such that*

$$\pi_i = \pi_{i-1} R_i, \quad i \geq 1, \quad (2)$$

where the matrix R_i records the expected number of visits to the set L_i between any two visits to the set L_{i-1} , and the sequence $\{R_i\}$ is the minimal nonnegative solution of the set of equations given by

$$R_i = A_0^{(i-1)} + R_i A_1^{(i)} + R_i R_{i+1} A_2^{(i+1)}, \quad i \geq 1.$$

Stated more precisely, $[R_i]_{j,k}$ is equal to the expected number of visits to $(i+1, k)$ before a return to the set $L_0 \cup L_1 \cup \dots \cup L_i$, provided the process starts in state (i, j) . Notice that the expected number of visits depends explicitly on the level i from which we start. To determine conditions for positive recurrence, we next discuss first passage times of $\{Z_n : n \geq 0\}$ and introduce some important matrices that are very similar to those typically used to characterize the behavior of level-independent QBD processes.

Suppose $\{Z_n : n \geq 0\}$ starts in some state (i, j) , that is, in level $i > 0$ and phase j at time 0, and define S_1 as the first return time to level i . That is,

$$S_1 \equiv \inf\{n \geq 1 : Z_n \in L_i | Z_0 = (i, j)\}.$$

Furthermore, adopting the notation in Ref. 1, let τ denote the first passage time of $\{Z_n : n \geq 0\}$ to level $i-1$. Define the following two probabilities:

$$[U_i]_{j,k} = \mathbb{P}(S_1 < \tau, Z_{S_1} = (i, k) | Z_0 = (i, j)), \quad (3)$$

$$[G_i]_{j,k} = \mathbb{P}(\tau < \infty, Z_\tau = (i-1, k) | Z_0 = (i, j)). \quad (4)$$

Note that Equations (3) and (4) bear a striking resemblance to Equations (6.5) and (6.6) of Ref. 1 with one major exception—the probabilities above depend explicitly on the level i whereas they are completely independent of i when the QBD is level independent. We shall see that this dependence significantly complicates the process of computing the limiting distribution of an LDQBD process. The (j, k) th element of the matrix U_i is the probability that, given we start in level i , the process returns to state i before hitting level $i-1$, and the (j, k) th element of G_i denotes the probability that the process hits level $i-1$ in a finite duration of time, given that it starts somewhere in level i . It is not surprising that the sequences of matrices, $\{R_i\}$, $\{G_i\}$, and $\{U_i\}$ are interrelated. In fact, any one of the sequences determines the other two as noted by Theorem 12.1.2 in Ref. 1, which is restated here without proof.

Theorem 2. *Any one of the sequences $\{R_i\}$, $\{G_i\}$, and $\{U_i\}$ determines the other two via the following set of relations:*

$$\begin{aligned} G_i &= (I - U_i)^{-1} A_2^{(i)}, \\ R_i &= A_0^{(i-1)} (I - U_i)^{-1}, \\ U_i &= A_1^{(i)} + A_0^{(i)} G_{i+1}, \\ U_i &= A_1^{(i)} + R_{i+1} A_2^{(i)}. \end{aligned}$$

Note that the same relationships hold for R , G , and U in the level-independent case wherein none of the matrices depend on the level i . For computational purposes, the following result, Theorem 12.1.3 of Ref. 1, shows the explicit relationship between these matrices:

Theorem 3. *For each $i \geq 1$, the matrices R_i , U_i , and G_i verify the following set of equations:*

$$\begin{aligned} G_i &= A_2^{(i)} + A_1^{(i)} G_i + A_0^{(i)} G_{i+1} G_i, \\ R_i &= A_0^{(i-1)} + R_i A_1^{(i)} + R_i R_{i+1} A_2^{(i+1)}, \\ U_i &= A_1^{(i)} + A_0^{(i)} (I - U_{i+1})^{-1} A_2^{(i+1)}. \end{aligned}$$

In light of the above two theorems and Equation (2), it is clear that the condition for positive recurrence can be restated in terms of the matrix G_1 . The following theorem provides the necessary and sufficient condition that ensures positive recurrence of P (see also Theorem 12.1.4 of Ref. 1).

Theorem 4. *The LDQBD process is positive recurrent if and only if there exists a strictly positive solution to the system of equations*

$$\pi_0 = \pi_0 (A_1^{(0)} + A_0^{(0)} G_1) \quad (5)$$

subject to the normalization condition

$$\pi_0 \left(\sum_{n=0}^{\infty} \prod_{i=1}^n R_i \right) \mathbf{e} = 1 \quad (6)$$

where the empty product (when $n = 0$) results in the identity matrix.

We pause here to remark that the matrix G_1 can only be obtained approximately in

practice; therefore, it is difficult to assert positive recurrence using Equations (5) and (6). However, the matrix equation (5) can be replaced by

$$\pi_0 = \pi_0 (A_1^{(0)} + R_1 A_2^{(1)}) \quad (7)$$

due to the equivalence of $A_0^{(0)} G_1$ and $R_1 A_2^{(1)}$. Note that, if $m = \infty$, then we also require that the embedded Markov chain on L_0 be positive recurrent. This condition is obviously met when $m < \infty$. Taken together, Equations (2), (6), and (7) provide the limiting distribution π . It is obvious that we must compute the family of matrices $\{R_i : i \geq 1\}$ to obtain this limiting distribution. By contrast, we need only to compute the matrix R (or G or U) in the level-independent case to completely characterize π . We will review some algorithmic approaches for both the level-independent and level-dependent versions later. First, we describe and review the continuous-time version of the LDQBD process, which parallels the discrete-time case.

CONTINUOUS-TIME LDQBD PROCESSES

The discrete-time LDQBD process has a natural analog in continuous time, which we now describe. Suppose $\{(X(t), J(t)) : t \geq 0\}$ is a continuous-time Markov process on the state space $S = \{(i, j) : i \geq 0, j = 1, 2, \dots, m\}$ where i denotes the level of the process and j denotes the phase. The infinitesimal generator matrix of the continuous-time LDQBD process is of the form

$$Q = \begin{bmatrix} A_1^{(0)} & A_0^{(0)} & 0 & 0 & \dots \\ A_2^{(1)} & A_1^{(1)} & A_0^{(1)} & 0 & \dots \\ 0 & A_2^{(2)} & A_1^{(2)} & A_0^{(2)} & \dots \\ 0 & 0 & A_2^{(3)} & A_1^{(3)} & \dots \\ \vdots & \vdots & \vdots & \vdots & \ddots \end{bmatrix}. \quad (8)$$

For each $i \geq 0$, the diagonal elements of $A_1^{(i)}$ are strictly negative, and the off-diagonal elements of $A_1^{(i)}$ are nonnegative. The matrices $A_0^{(i)}$ and $A_2^{(i)}$ are nonnegative. For $i \geq 1$, the matrix $A^{(i)} = A_0^{(i)} + A_1^{(i)} + A_2^{(i)}$ has zero row sums as does the matrix $A_0^{(0)} + A_1^{(0)}$. The structure of the generator matrix Q reveals that

its transitions, like the discrete-time counterpart, are restricted to nearest neighbors in the levels and unrestricted (in general) across the phase dimension. For $i \geq 1$, the process transitions from (i, j) to $(i-1, k)$ at rate $[A_2^{(i)}]_{j,k}$, it transitions to state $(i+1, k)$ with rate $[A_0^{(i)}]_{j,k}$, or to state (i, k) at rate $[A_1^{(i)}]_{j,k}$. Finally, from state $(0, j)$, the process transitions to $(1, k)$ at rate $[A_0^{(0)}]_{j,k}$, or to state $(0, k)$ with rate $[A_1^{(0)}]_{j,k}$. If the process possesses a limiting distribution, $\pi = (\pi_0, \pi_1, \pi_2, \dots)$, then it must satisfy the system of equations $\pi Q = \mathbf{0}$ and $\pi e = 1$, where $\mathbf{0}$ denotes the zero vector. We next review the necessary and sufficient condition for positive recurrence of the LDQBD process in continuous time and provide an expression for its limiting distribution.

Positive Recurrence and Limiting Distribution

As one might expect, the limiting distribution of the continuous-time version is analogous to its discrete-time counterpart. For the discussion that follows, we assume that $\{(X(t), J(t)) : t \geq 0\}$ with generator matrix Q is irreducible. The following main result shows that the limiting distribution restricted to any one of the levels depends explicitly on π_0 .

Theorem 5. *The LDQBD process with infinitesimal generator matrix given by Equation (8) is positive recurrent if and only if there exists a strictly positive solution to the system of equations*

$$\pi_0 (A_1^{(0)} + R_0 A_2^{(1)}) = \mathbf{0} \quad (9)$$

subject to the normalization condition

$$\pi_0 \left(\sum_{i=0}^{\infty} \prod_{n=0}^{i-1} R_n \right) e = 1. \quad (10)$$

In such a case, the m -order row vector π_i is given by

$$\pi_i = \pi_0 \prod_{n=0}^{i-1} R_n, \quad i \geq 0. \quad (11)$$

In Equations (10) and (11), when $i = 0$, the empty product results in the identity matrix I .

As for the discrete-time version, the limiting distribution is characterized by a level-dependent sequence of matrices $\{R_i : i \geq 0\}$ which, in general, can only be determined numerically. The elements of these matrices can be interpreted as follows. The (j, k) th element of R_i , denoted by $[R_i]_{j,k}$, is the expected sojourn time in state $(i+1, k)$ per unit sojourn in state (i, j) , given that the process started in state (i, j) . It is well known (cf. Bright and Taylor [3]) that the sequence $\{R_i\}$ is the minimal nonnegative solution of the set of equations

$$A_0^{(i)} + R_i A_1^{(i+1)} + R_i (R_{i+1} A_2^{(i+2)}) = 0, \quad i \geq 0. \quad (12)$$

If the number of levels and/or phases is infinite, computing the limiting distribution has two major complications. First, one must truncate the infinite series of Equation (10) in an appropriate manner, and second, the matrices $\{R_i : i \geq 0\}$ must be computed efficiently. The next section provides a brief overview of some of the algorithmic approaches to computing the limiting distribution of the discrete- and continuous-time LDQBD processes.

NUMERICAL ALGORITHMS

Numerical approaches for obtaining the limiting distribution of level-independent QBD processes have been studied fairly extensively in the literature. For both discrete- and continuous-time cases, Neuts [4] provides some methods for determining positive recurrence and computing the limiting distribution. Hajek [5] considered the case of homogeneous QBD processes with a finite number of levels and showed that the limiting distribution vector can be described by the sum of two matrix-geometric terms. For general, level-independent QBD processes, most noteworthy is the logarithmic reduction algorithm developed in 1993 by Latouche and Ramaswami [6], which guarantees quadratic convergence of the solution for the matrix R in level-independent QBD processes. A method for computing the stationary distribution of

finite level-independent QBD processes was contributed by Elhasfi and Molle [7]. Some software tools that implement the most popular algorithms have been contributed by various researchers [8–11].

For the level-dependent case, a few approaches are noteworthy. When the number of levels and the number of phases are both finite, Gaver *et al.* [12] provide stable algorithms for computing the limiting distribution and moments of first passage times in the continuous-time case. These algorithms are similar to the linear iteration schemes developed by Latouche and Ramaswami [13] who show how to use logarithmic reduction to compute the moments of passage times for level-independent processes. Ye and Li [14] developed the “folding algorithm” to compute the limiting distribution of a finite continuous-time LDQBD process. Their efficient algorithm directly solves $\pi Q = 0$ by employing state-space reduction techniques that reduce the complexity induced by level dependence. Li and Cao [15] developed two types of RG-factorizations in order to analyze LDQBD processes with either finitely or infinitely many levels. They use their factorizations to derive the Laplace transforms of the conditional distributions of integral functionals of QBD processes.

When the number of levels and/or phases is infinite, the most widely accepted approach for computing the limiting distribution is due to Bright and Taylor [3,16] who provide an extension of the logarithmic reduction algorithm of Latouche and Ramaswami [6] for the level-dependent case. Define the continuous-time LDQBD process $\{Z(t) : t \geq 0\} \equiv \{(X(t), J(t)) : t \geq 0\}$ on the state space $\{(i, j) : i \geq 0, 1 \leq j \leq M_i\}$ where M_i is the number of phases in level i , which can be infinite. Bright and Taylor [3] suggest truncating the infinite series of Equation (10) at some level K and then renormalizing to compute an approximate subvector of the form

$$\pi_i(K) = \pi_0(K) \prod_{n=0}^{i-1} R_n, \quad i \geq 1,$$

such that $\pi_0(K)$ satisfies Equation (9) and the normalization condition,

$$\pi_0(K) \sum_{i=0}^K \left[\prod_{n=0}^{i-1} R_n \right] \mathbf{e} = 1.$$

The subvectors, $\{\pi_i(K) : i \geq 0\}$, represent an invariant measure for the limiting distribution of all the states at or below level K . Therefore, for any $K \geq 0$, $\pi_i(K)$ is an upper bound for π_i (componentwise), and $\pi_i(K) \rightarrow \pi_i$ as $K \rightarrow \infty$.

In order to compute $\pi_i(K)$ for a chosen truncation level K , Bright and Taylor [3] examine the discrete-time Markov chain embedded at the jump epochs of $\{Z(t) : t \geq 0\}$ to compute the family of matrices $\{R_i : i \geq 0\}$ using a recursive scheme. The following result (Lemma 1 of Ref. 3) is a continuous-time extension of a discrete-time result stated by Ramaswami and Taylor [17].

Lemma 1. *If $\{Z(t) : t \geq 0\}$ is positive recurrent, then for $i \geq 0$ the matrix R_i is given by*

$$R_i = \sum_{\ell=0}^{\infty} U_i^{\ell} \prod_{n=0}^{\ell-1} D_{k+2^{\ell-1}}^{\ell-1-n}, \quad i \geq 0 \quad (13)$$

where, for $i \geq 1$, U_i^{ℓ} and D_i^{ℓ} are $M_{i-1} \times M_{i-1+2^{\ell}}$ and $M_{i-1} \times M_{i-1-2^{\ell}}$ matrices, respectively, that are recursively defined by

$$\begin{aligned} U_i^0 &= A_0^{(i)} \left(-A_1^{(i+1)} \right)^{-1}, \\ D_i^0 &= A_2^{(i)} \left(-A_2^{(i-1)} \right)^{-1}, \\ U_i^{\ell+1} &= U_i^{\ell} U_{i+2^{\ell}}^{\ell} \left[I - U_{i+2^{\ell+1}}^{\ell} D_{i+3 \cdot 2^{\ell}}^{\ell} \right. \\ &\quad \left. - D_{i+2^{\ell+1}}^{\ell} U_{i+2^{\ell}}^{\ell} \right]^{-1}, \\ D_i^{\ell+1} &= D_i^{\ell} D_{i-2^{\ell}}^{\ell} \left[I - U_{i-2^{\ell+1}}^{\ell} D_{i-2^{\ell}}^{\ell} \right. \\ &\quad \left. - D_{i-2^{\ell+1}}^{\ell} U_{i-3 \cdot 2^{\ell}}^{\ell} \right]^{-1}. \end{aligned}$$

The infinite series of Equation (13) can be truncated using a simple scheme (see Algorithms 2 and 3 of Ref. 3). By rearranging the terms in Equation (12), the family of

matrices, $\{R_i : i \geq 0\}$, can be recursively computed by

$$R_i = A_0^{(i)} \left(-A_1^{(i+1)} - R_{i+1} A_2^{(i+2)} \right)^{-1} \quad (14)$$

(assuming the inverse exists) so that Equation (13) need not be computed repeatedly. Algorithm 1 of Ref. 3 can be used to compute $\pi_i(K)$ for a chosen value K . This algorithm is summarized in what follows.

Computing $\pi(K)$ for Given K .

- Step 1: Calculate R_{K-1} using Equation (13).
 Step 2: Recursively calculate $R_{K-2}, R_{K-3}, \dots, R_0$ using Equation (14).
 Step 3: Solve the system of equations

$$\pi_0(K) \left[A_1^{(0)} + R_0 A_2^{(1)} \right] = \mathbf{0}, \quad \pi_0(K) \mathbf{e} = 1.$$

- Step 4: For $i = 1$ to K , set

$$\pi_i(K) = \pi_{i-1}(K) R_{i-1},$$

and normalize $\pi_n(K)$, $n = 0, 1, \dots, i$, so that

$$\sum_{n=0}^i \pi_n(K) \mathbf{e} = 1.$$

Algorithms 2 and 3 of Ref. 3 provide the means by which to truncate the infinite series of Equation (13) to effectively compute R_{K-1} in Step 1.

It is imperative to select an integer K that is large enough to ensure that the limiting probability of being in a state at or above level K is close to zero. Algorithm 4 of Ref. 3 describes a general method for choosing a truncation point that works well in practice. We next review the main steps of this algorithm.

Selecting the Integer K .

- Step 1: Set $K_0 = 0$.
 Step 2: Do the following:
 a. Choose K_1 such that $K_1 > K_0$.
 b. Calculate five terms of Equation (13) for R_{K_1-1} .

- If the five terms are sufficient, go to Step 2(c),
- else repeat Steps 2(a) and 2(b).
- c. Recursively calculate $R_{K_1-2}, R_{K_1-3}, \dots, R_{K_0}$ using Equation (14).
- d. Simultaneously solve

$$\pi_0(K_1) \begin{bmatrix} A_1^{(0)} + R_0 A_2^{(1)} \end{bmatrix} = \mathbf{0}, \quad \pi_0(K_1) \mathbf{e} = 1.$$

- e. For $i = K_0 + 1$ to K_1 , do

$$\pi_i(K_1) = \pi_{i-1}(K_1) R_{i-1},$$

and normalize $\pi_n(K)$, $n = 0, 1, \dots, i$, such that

$$\sum_{n=0}^i \pi_n(K_1) \mathbf{e} = 1.$$

- f. Set $K_0 = K_1$ until $\pi_{K_1}(K_1) \mathbf{e} < \epsilon$.

Step 3: Set $K = K_1$.

Besides this general procedure for determining K and the subvectors $\{\pi_i(K) : i \geq 0\}$, Bright and Taylor [3] also provide algorithms for some special cases including LDQBD processes with a large number of boundary states (Algorithm 5) and those which are stochastically dominated by another LDQBD process (Algorithms 6 and 7). The former is a type of LDQBD process that exhibits level-dependent behavior up to some fixed level $\bar{K}$, and level-independent behavior for each level i such that $i > \bar{K}$ [4].

FURTHER READING AND APPLICATIONS

For extensive coverage of the level-independent QBD process in discrete and continuous time, it is best to first consult the two major texts due to Neuts [4,18] and one due to Latouche and Ramaswami [1]. For a cogent summary of the level-independent case, please see *Level-Independent Quasi-Birth-and-Death Processes*, which provides the main results for limiting distributions and conditions for positive recurrence, as well as a more detailed discussion of algorithmic procedures for computing

the limiting distribution. The best reference for understanding the rudimentary aspects of the LDQBD process is Chapter 12 of the excellent text by Latouche and Ramaswami [1], which considers (primarily) the discrete-time version of the model. As noted above, the two papers by Bright and Taylor [3,16] provide the details of an efficient algorithm for computing the limiting distribution of the infinite state-space, continuous-time model.

Over the years, several extensions have been developed for both the level-independent and LDQBD processes. One of the most important and interesting extensions of level-independent QBD processes is due to Ramaswami [19] who showed connections to the analysis of stochastic fluid queueing models. A stochastic fluid queueing model can be viewed as a QBD process wherein the level assumes values on the nonnegative real line and the phase variable is discrete. The fluid level evolves in a piecewise linear manner depending on the current phase. Subsequent contributions to fluid queues include Ahn and Ramaswami [20] and Bean *et al.* [21,22]. Of particular interest is the recent paper by da Silva Soares and Latouche [23] who analyze level-dependent fluid models within the QBD paradigm. Bean *et al.* [24] provide a complete quasistationary analysis of the discrete-time LDQBD process by assuming that level 0 behaves as an absorbing state. Choi *et al.* [25] provide a generalization of finite LDQBD processes that they call “nested QBD chains,” which entail the addition of a third dimension, the period. They provide the fundamental matrices for these types of chains and prove other interesting properties as well.

The LDQBD process finds wide applicability as a model for systems with complex dynamics. It is most prevalent in the modeling of queueing systems with Markovian arrival process (MAP) input, or for those with phase-type distributions. For example, the LDQBD process is ideal for modeling the $PH/M/\infty$ queue. Some other interesting applications in queueing theory include models described in Refs 26–30. The emergence of the service sector in many economies has sparked a renewed interest in retrial queueing models. These models can help assess the

impact of retrial customers who are initially denied access to service but who retry the system after some random amount of time. Such models are particularly important in large-scale service systems, such as large customer contact centers. Consequently, many new single- and multiserver retrial queueing models have emerged over the past five years. The infinitesimal generator matrix of retrial queues is usually of the LDQBD type because the retrial rate varies with the level (which corresponds to the number of customers in orbit). Some notable LDQBD retrial queueing models can be found in Refs 31–39. In addition to queueing models, LDQBD processes are now emerging in reliability modeling and analysis and inventory systems modeling. Some interesting reliability applications are due to Pérez-Ocón and Montoro-Cazorla [40,41]. Recent inventory models that exploit the LDQBD structure can be found in Refs 42 and 43. The homogeneous QBD process has found wide applicability in the modeling and analysis of computer and communications systems, and Bright and Taylor [3] provide numerous examples of such. Recently, LDQBD processes have been applied as models of real-time wireless code division multiple access (WCDMA) communications systems to estimate performance parameters such as blocking probability and expected delay [44,45].

LEVEL-INDEPENDENT QUASI-BIRTH-AND-DEATH PROCESSES

GUY LATOUCHE

Faculté des sciences, Université
Libre de Bruxelles, Bruxelles,
Belgium

Quasi-birth-and-death (QBD) processes are Markovian processes on a two-dimensional state space and their characteristic feature is that, in one of the dimensions, transitions are allowed only to the nearest values. To fix the ideas, consider that the state space is a strip of the form $S = \{(n, i) : n \geq 0, 1 \leq i \leq m\}$; the process may move from (n, i) to states of the form (n, j) or $(n - 1, j)$ or $(n + 1, j)$, but not to any state of the form $(n \pm k, j)$ where $k \geq 2$. In the first dimension, the process behaves like a birth-and-death process [1], which explains the origin of the name *quasi-birth-and-death* coined by Wallace [2].

The component n in the state (n, i) is usually called the *level* and the component i is called the *phase*. A QBD is *level independent* if the rates at which transitions occur do not depend on the level, although they may depend on the phase. Thus, a level-independent QBD is like an M/M/1 queue [1] where the rates of increase or decrease are constant. Processes for which the transitions do depend on the level are called *level-dependent QBD processes* [1].

Level-independent QBDs furnish one of the best illustrations of the *matrix-analytic method*, a type of mathematical analysis that combines analytic developments—mostly based on probabilistic reasoning and linear algebraic formulation—and algorithmic considerations. QBDs were first studied by Evans [3] and later by Neuts [4,5] who set a major research program in motion.

This article contains the basic material about QBDs: the results and algorithms that are of most immediate use for anyone using a QBD model.

DEFINITIONS

A *discrete-time*, level-independent QBD process is defined as a Markov chain $\{X_t : t \in \mathbb{N}\}$ on the state space $S = \{(n, i) : n \geq 0, 1 \leq i \leq m\}$ where m may be finite or infinite. We order the state space in lexicographic order and we write the transition matrix P as

$$P = \begin{bmatrix} B & A_1 & & & 0 \\ A_{-1} & A_0 & A_1 & & \\ & A_{-1} & A_0 & A_1 & \\ & & A_{-1} & A_0 & \ddots \\ 0 & & & \ddots & \ddots \end{bmatrix}, \quad (1)$$

where A_{-1} , A_0 , A_1 , and B are nonnegative matrices of order m , and the row-sums of P are all equal to 1, which means that the row-sums of $A_{-1} + A_0 + A_1$ and those of $B + A_1$ are also equal to 1.

From the structure of P , one sees that the Markov chain is restricted in its transitions: from the state (n, i) with $n \geq 1$, it may move to $(n - 1, j)$ with probability $(A_{-1})_{ij}$, or to (n, j) with probability $(A_0)_{ij}$, or to $(n + 1, j)$ with probability $(A_1)_{ij}$, independent of n ; for $n = 0$, the feasible transitions are from $(0, i)$ to $(1, j)$ with probability $(A_1)_{ij}$, and to $(0, j)$ with probability B_{ij} .

In many applications, the component n of the state is the number of customers in some queue and for that reason it is called the *level*. The component j is some auxiliary information, such as the environment phase in the M/M/1 queue in a random environment of Neuts [5], or the content of the intermediary buffer in the tandem system of Latouche and Neuts [6], or even a whole network of queues, as in Ramaswami and Taylor [7]. The second component is usually called the *phase*, unless one is dealing with a specific application that requires a more precise terminology. As the examples cited show, the phase may take values in a more or less complicated set of values; the important feature is that this set should be denumerable, so that we may

number its elements from 1 to $m \leq \infty$.

It may happen that B is equal to $A_{-1} + A_0$, but this is not always the case; furthermore, it may be that the system adopts a very different behavior when the main queue is empty, then the transition matrix takes the slightly different form

$$P = \begin{bmatrix} B_0 & B_1 & & 0 \\ B_{-1} & A_0 & A_1 & \\ & A_{-1} & A_0 & A_1 \\ & & A_{-1} & A_0 & \ddots \\ 0 & & & \ddots & \ddots \end{bmatrix}, \quad (2)$$

where B_0 is a square matrix of order m_0 , possibly different from m , in which case B_1 and B_{-1} would be rectangular matrices of appropriate dimensions.

A *continuous-time* level-independent QBD is defined in the same manner. The major difference is that its dynamics is characterized by an infinitesimal generator Q instead of a transition probability matrix P , with

$$Q = \begin{bmatrix} B & A_1 & & 0 \\ A_{-1} & A_0 & A_1 & \\ & A_{-1} & A_0 & A_1 \\ & & A_{-1} & A_0 & \ddots \\ 0 & & & \ddots & \ddots \end{bmatrix}. \quad (3)$$

The structure is the same as Equation (1), the difference being that the diagonal elements of B and of A_0 are strictly negative, that all the off-diagonal elements are nonnegative and that the row-sums of $A_{-1} + A_0 + A_1$ and of $B + A_1$ are zero.

We shall assume throughout this article that the QBD is irreducible: from any state, any other state may be reached after a finite number of transitions. We shall also assume here that the matrix $A = A_{-1} + A_0 + A_1$ is irreducible.

STABILITY CONDITION

A basic question is whether the states of the QBD are positive recurrent, null recurrent, or transient. A simple condition is expressed in terms of the stationary probability vector

α of the matrix A , if it exists. In discrete time, α is the unique solution of the system $\alpha^t A = \alpha^t$, $\alpha^t \mathbf{1} = 1$, where α^t is the transpose of α for any vector α , and $\mathbf{1}$ is a vector of 1's. In continuous time, α is the unique solution of the system $\alpha^t A = 0$, $\alpha^t \mathbf{1} = 1$.

The following property holds both in discrete- and in continuous time.

Theorem 1 [4, Chapter 1; 8, Chapter 7]. *Assume that the QBD is irreducible, that m is finite, and that the matrix A is irreducible, with stationary probability vector α . Define $\mu = \alpha^t A_1 \mathbf{1} - \alpha^t A_{-1} \mathbf{1}$. The QBD is positive recurrent if and only if $\mu < 0$; it is null recurrent if $\mu = 0$, and it is transient if $\mu > 0$.*

Other stability conditions are given in Latouche and Taylor [9]; if m is infinite, or if the matrix A is not irreducible, the conditions for stability are more complex and we refer the reader to Tweedie [10] and to Ref. 8, Chapter 7.

STATIONARY DISTRIBUTION

Discrete Time

We assume in this section that the system is positive recurrent. Quite naturally, we subdivide the stationary probability vector π into smaller vectors $\pi_0, \pi_1, \pi_2, \dots$, of size m , where π_n is the subvector of stationary probabilities for the states $(n, 1), \dots, (n, m)$ in level n . A remarkable fact is that the stationary distribution has a *matrix-geometric* form—the object of the next theorem.

Theorem 2 [4, Chapter 1; 8, Chapter 6]. *If the discrete-time QBD with transition matrix (Eq. 1) is positive recurrent, then there exists a nonnegative matrix R such that*

$$\pi_n^t = \pi_0^t R^n, \quad \text{for } n \geq 0. \quad (4)$$

The vector π_0 is the unique solution of the system

$$\pi_0^t (B + R A_{-1}) = \pi_0^t, \quad \pi_0^t \left(\sum_{k=0}^{\infty} R^k \right) \mathbf{1} = 1. \quad (5)$$

The matrix R is the minimal nonnegative solution of the matrix-quadratic equation

$$X = A_1 + XA_0 + X^2A_{-1} \quad (6)$$

and it has the following interpretation: for each pair of phases i and j , R_{ij} is the conditional expected number of times that the QBD visits the state $(1, j)$ until the next return to any of the states in level 0, given that the QBD is in state $(0, i)$ at time 0.

The stationary distribution is characterized by the subvector π_0 and by the matrix R , and π_0 itself is the solution of a known linear system, once R is known. This explains why a great deal of attention has been given in the literature on QBDs to methods to compute R in as efficient a manner as possible, a topic to which we return in the section titled “Algorithms.”

If the transition matrix is given by Equation (2) instead of Equation (1), we still have that $\pi_n = \pi_{n-1}R$, for $n \geq 2$, where R is the same as in Theorem 2, but the subvectors π_0 and π_1 are now given by the system

$$\begin{bmatrix} \pi_0^t & \pi_1^t \end{bmatrix} \begin{bmatrix} B_0 & B_1 \\ B_{-1} & A_1 + RA_{-1} \end{bmatrix} = \mathbf{0},$$

$$\pi_0^t \mathbf{1} + \pi_1^t \left(\sum_{k=0}^{\infty} R^k \right) \mathbf{1} = 1. \quad (7)$$

Here, π_0 is of size m_0 and π_1 is of size m .

Continuous Time

In continuous time, the results are very much the same, only a few details needing to be changed, because the stationary probability is characterized by the slightly different system $\pi^t Q = \mathbf{0}$, $\pi^t \mathbf{1} = 1$, where Q is the infinitesimal generator of the process.

Theorem 3 [4, Chapter 1; 8, Chapter 6]. Assume that the continuous-time QBD with transition matrix (Eq. 3) is positive recurrent. There exists a nonnegative matrix R such that

$$\pi_n^t = \pi_0^t R^n, \quad \text{for } n \geq 0. \quad (8)$$

The vector π_0 is the unique solution of the system

$$\pi_0^t (B + RA_{-1}) = \mathbf{0}, \quad \pi_0^t \left(\sum_{k=0}^{\infty} R^k \right) \mathbf{1} = 1. \quad (9)$$

The matrix R is the minimal nonnegative solution of the matrix-quadratic equation

$$A_1 + XA_0 + X^2A_{-1} = 0 \quad (10)$$

and it has the following interpretation: for each pair of phases i and j , R_{ij} is the rate at which the QBD visit the state $(1, j)$, per unit of time spent in $(0, i)$.

Observe that if $m < \infty$, the series in Equations (5), (7), and (9) is actually equal to $\sum_{k=0}^{\infty} R^k = (I - R)^{-1}$; if $m = \infty$, the series is the minimal nonnegative solution of the system $X(I - R) = I$.

Furthermore, if $m < \infty$, the convergence of the series indicates that the modulus of all the eigenvalues of R is strictly less than one or, equivalently, that $\text{sp}(R) < 1$, where $\text{sp}(\cdot)$ is the spectral radius. For transient or null-recurrent QBDs, we have $\text{sp}(R) = 1$.

FIRST PASSAGE DOWNWARD

Besides the matrix R , two transition probability matrices play an important role in the theory of QBDs; the first is defined as follows. Let T denote the first passage time to level 0, and define

$$G_{ij} = \Pr[T < \infty, X_T = (0, j) | X_0 = (1, i)], \quad (11)$$

for $1 \leq i, j \leq m$. In words, G_{ij} is the conditional probability that the QBD eventually visits level 0, and that $(0, j)$ is the first state

visited there, given that the process starts in phase i in level 1.

In queueing applications, T would be the length of a busy period and G would indicate whether such a busy period terminates with probability one or not and what is the state of the remainder of the system, upon completion of the busy period.

Theorem 4 [4, Chapter 3; 8, Chapter 8].

In discrete time, the matrix G is the minimal nonnegative solution of the equation

$$X = A_{-1} + A_0X + A_1X^2. \quad (12)$$

In continuous time, G is the minimal nonnegative solution of

$$A_{-1} + A_0X + A_1X^2 = 0. \quad (13)$$

In both cases, G is stochastic if the QBD is recurrent.

The similarity between Equations (6) and (12), and (10) and (13) suggests that there is a strong connection between the matrices R and G . This is made explicit through the introduction of a third matrix.

In *discrete time*, let θ be the first return time to level 1 and define

$$U_{ij} = \Pr[\theta < \infty, \theta < T, X_\theta = (1, j) | X_0 = (1, i)], \quad (14)$$

for $1 \leq i, j \leq m$. In words, U_{ij} is the probability of the following event: starting from $(1, i)$, the QBD eventually returns to level 1 before it visits any state in level 0, and it visits $(1, j)$ upon its return to level 1.

The matrix U is the transition matrix of the transient Markov chain embedded at those epochs when the QBD visits level 1 under taboo of level 0. It is transient because the QBD either eventually visits level 0 or it drifts to infinity and ceases to return to level 1, in both cases the taboo chain stops.

In *continuous time*, we define the censored Markov process of intervals of sojourn in the states of level 1, under taboo of the first visit to level 0, and we define U as the infinitesimal generator of that process.

Theorem 5 [8, Chapter 6]. *In both discrete- and continuous time,*

$$U = A_0 + A_1G. \quad (15)$$

In discrete time, $R = A_1 \sum_{k=0}^{\infty} U^k$, which is equivalent to

$$R = A_1(I - U)^{-1} \quad (16)$$

if $m < \infty$.

In continuous time, $R = A_1 \int_0^{\infty} e^{Ut} dt$, which is equal to

$$R = A_1(-U)^{-1} \quad (17)$$

if $m < \infty$.

ALGORITHMS

We address here the question of actually computing the matrix R ; this requires that m be finite so that calculations are feasible, and for that reason we assume throughout this section that $m < \infty$. Furthermore, as we have seen in the preceding two sections, the equations for discrete- and for continuous-time QBDs are very similar, which is why we restrict our attention to the discrete-time case for the most part.

Early efforts concentrated on directly solving Equation (6) [4, Chapter 1], since then, the focus has shifted to Equation (12). This is due to the fact that the three matrices R , G , and U are linked together by a number of equations, of which the following two are particularly useful:

$$G = (I - U)^{-1}A_{-1} \quad U = A_0 + RA_{-1}. \quad (18)$$

Together with Equations (15) and (16), these equations show that R , G , and U carry the same information and that one may compute any two of them from the third.

The main reason for working with Equation (12) instead of Equation (6) is that G is a stochastic or a substochastic matrix, which imposes stronger constraints on the solution of Equation (12). For that reason, we focus on algorithms to compute G , knowing

that Equations (15) and (16) allow us to easily compute R afterwards. We emphasize, however, that every algorithm designed for G has a twin algorithm which works for R , see Bini *et al.* [11, Section 5.3], Latouche [12], Latouche and Ramaswami [13], Neuts [4], and Ramaswami [14].

Basic Algorithms

It is simplest to use one of the defining equations for G , to start from an appropriate initial value and to proceed by successive substitutions. Thus, using Equation (12), one proves that the sequence

$$\begin{aligned} G_0 &= 0, \\ G_{n+1} &= A_{-1} + A_0 G_n + A_1 G_n^2, \end{aligned} \quad (19)$$

for $n \geq 0$ monotonically converges to G . Moreover, if the QBD under study is recurrent, then G is stochastic and one may stop the computation of the successive approximations as soon as they are sufficiently close to being stochastic.

If the QBD is recurrent there is some advantage in starting the iteration with a stochastic matrix. Some care must be used in choosing G_0 , but the identity matrix is always suitable so that the sequence

$$\begin{aligned} G_0 &= I, \\ G_{n+1} &= A_{-1} + A_0 G_n + A_1 G_n^2, \end{aligned} \quad (20)$$

for $n \geq 0$ also converges to G ; the convergence in this case is not monotone, but the final result is obtained with fewer iterations than with Equation (19).

If we use the pair of Equations (15) and (18), we obtain two linked sequences, one for U and one for G :

$$\begin{aligned} G_0 &= 0, \\ U_n &= A_0 + A_1 G_{n-1}, \\ G_n &= (I - U_n)^{-1} A_{-1}, \end{aligned} \quad (21)$$

for $n \geq 1$. Here, again the sequence $\{G_n\}$ monotonically converges to G , and here also

one may accelerate the procedure by starting with $G_0 = I$.

The sequence (Eq. 21) has two advantages over Equation (19). First, it converges faster, sometimes much faster. Secondly, it is amenable to a very simple interpretation in terms of the dynamic behavior of the QBD: the matrix G_n gives the first passage probabilities from level 1 to level 0 under the additional constraint that the QBD is not allowed to reach up beyond level n . With this interpretation, it is obvious that the sequence should be monotone and convergent.

The convergence rate of Equation (21) happens to be equal to $\text{sp}(R)$ which, as we have seen at the end of the section titled “Stationary Distribution,” is strictly less than 1 for positive recurrent QBDs and equal to 1 in the null recurrent and in the transient cases. One should, therefore, expect that the algorithms require large numbers of iterations when the parameters of the QBD are at the boundary of its stability region.

One may also mention that the algorithms are usually numerically stable; this is due to the fact that one is computing at each step a transition probability matrix for a well-behaved system. Further details are to be found in Ref. 11, Chapter 6, and also in Refs 8, Chapter 8 and 4, Chapter 3.

In continuous time, G is given as

$$G = (-U)^{-1} A_{-1}, \quad (22)$$

instead of Equation (18), and we may combine this equation with Equation (15) to construct the sequence

$$\begin{aligned} G_0 &= 0, \\ U_n &= A_0 + A_1 G_{n-1}, \\ G_n &= (U_n)^{-1} A_{-1}, \end{aligned} \quad (23)$$

for $n \geq 1$; its convergence and stability properties closely mimic those of Equation (21).

Quadratic Algorithms

In time, a number of algorithms have been proposed, which have quadratic convergence. Two popular ones, called the *Logarithmic* and

the *Cyclic reduction* algorithms are nearly identical. In short, they compute quantities similar to the first approximation $(I - A_0 - A_1)^{-1}A_{-1}$ in Equation (21), for a sequence of *new QBDs*, one level of the n th QBD corresponding to 2^n levels of the original one. This gives extremely efficient, quadratically convergent procedures. For cyclic reduction, which is slightly more efficient than logarithmic reduction, the successive approximations $G^{(0)}, G^{(1)}, G^{(2)}, \dots$ are given as

$$G^{(n)} = (I - \widehat{A}_0^{(n)})^{-1}A_{-1}, \quad (24)$$

where

$$\widehat{A}_0^{(0)} = A_0, \quad A_i^{(0)} = A_i, \quad \text{for } i = -1, 0, 1,$$

and

$$\begin{aligned} \widehat{A}_0^{(n+1)} &= \widehat{A}_0^{(n)} + A_1^{(n)}(I - A_0^{(n)})^{-1}A_{-1}^{(n)} \\ A_{-1}^{(n+1)} &= A_{-1}^{(n)}(I - A_0^{(n)})^{-1}A_{-1}^{(n)} \\ A_0^{(n+1)} &= A_0^{(n)} + A_1^{(n)}(I - A_0^{(n)})^{-1}A_{-1}^{(n)} \\ &\quad + A_{-1}^{(n)}(I - A_0^{(n)})^{-1}A_1^{(n)} \\ A_1^{(n+1)} &= A_1^{(n)}(I - A_0^{(n)})^{-1}A_1^{(n)} \end{aligned}$$

for $n \geq 0$.

As each iteration in the sequences (Eqs 19, 21, and 24) requires a few matrix products and the resolution of linear systems of order m , the numerical complexity is $O(m^3)$ per iteration in all cases. The difference in efficiency is determined by the coefficient of m^3 —which is slightly lower for the two linear algorithms—and by the number of iterations—which is much lower for the other two.

Tools

The algorithms above have been the object of tools, some of which are available through the Web [15–18].

Spectral Decomposition

As mentioned above, many authors have proposed other algorithms to determine

the stationary distribution of QBDs; for instance, Grassmann and Heyman [19] developed computational procedures that are similar to Equation (21).

A different class of methods have made use of the fact that the spectral decomposition of R , as well as that of G , can be obtained directly from the polynomial matrix

$$\begin{aligned} \Gamma(x) &= A_{-1} + x(A_0 - I) + x^2A_1 \\ &= (xA_1 + A_0 + A_1G - I)(xI - G) \end{aligned} \quad (25)$$

(in discrete time). The polynomial $\det \Gamma(x)$ has the $2m$ zeros

$$\xi_1 \leq \xi_2 \leq \dots \leq \xi_m \leq \xi_{m+1} \leq \dots \leq \xi_{2m},$$

counting $2m - r$ zeros at infinity if the degree of $\det \Gamma(x)$ is $r < 2m$.

Theorem 6. *For a discrete-time QBD with finitely many phases, under suitable irreducibility assumptions, the roots ξ_1 to ξ_m are the eigenvalues of G and the roots ξ_{m+1} to ξ_{2m} are the reciprocals of the eigenvalues of R . Moreover,*

- $\xi_m = 1 < \xi_{m+1}$ if the QBD is positive recurrent,
- $\xi_m = 1 = \xi_{m+1}$ if the QBD is null recurrent,
- and $\xi_m < \xi_{m+1} = 1$ if the QBD is transient.

A very thorough analysis is found in Gail *et al.* [20] and the references therein, and a summary in Ref. 8, Chapter 9. This is more of theoretical than practical interest, although some authors have made use of it in order to solve specific models, see Mitrani [21], for instance.

Another method based on spectral decomposition has been developed by Akar and Sohraby [22] and named the *invariant subspace* approach. It is shown in Bini *et al.* [23] to be a mirror image of cyclic reduction, after applying a transformation that unfortunately removes all probabilistic significance.

EXAMPLE

We conclude with an illustrative example of a single server queue in a random environment of four phases. At each transition, three events are possible:

- a service completion, with probability p_μ , provided the queue is not empty;
- an arrival, with probability p_λ if the system is in one of the phases 1, 2, or 3, and with probability p_Λ if the system is in phase 4;
- a change of phase with probability p_γ , the phases changing cyclically in the order 1, 2, 3, 4, 1, ...

The transition blocks are given below:

$$A_{-1} = p_\mu I, \quad A_0 = \begin{bmatrix} r_a & p_\gamma & & \\ & r_a & p_\gamma & \\ & & r_a & p_\gamma \\ p_\gamma & & & r_b \end{bmatrix},$$

$$A_1 = \begin{bmatrix} p_\lambda & & & \\ & p_\lambda & & \\ & & p_\lambda & \\ & & & p_\Lambda \end{bmatrix},$$

and $B = A_{-1} + A_0$, where $r_a = 1 - p_\mu - p_\gamma - p_\lambda$, and $r_b = 1 - p_\mu - p_\gamma - p_\Lambda$.

The stationary probability vector of A is uniform and, by Theorem 1, the queue is positive recurrent if $p_\mu > 0.75p_\lambda + 0.25p_\Lambda$ or, equivalently, if the traffic coefficient ρ defined as $(0.75p_\lambda + 0.25p_\Lambda)/p_\mu$ is strictly less than 1.

We have chosen the following values for the parameters: $p_\mu = 0.1$, $p_\gamma = 0.02$, $p_\lambda = 0.02$, and $p_\Lambda = 0.2$, which gives $\rho = 0.65$, a moderately loaded queue. Thus, a cycle through the four phases takes 200 units of time on average and the probability of an arrival increases by a factor of 10 in phase 4, so that the queue is pushed toward high values.

We have used the logarithmic reduction algorithm and asked for a precision of 10^{-8} . The algorithm requires seven iterations and

yields the matrices

$$G = \begin{bmatrix} 0.810 & 0.152 & 0.034 & 0.004 \\ 0.012 & 0.816 & 0.156 & 0.016 \\ 0.052 & 0.037 & 0.833 & 0.078 \\ 0.259 & 0.174 & 0.122 & 0.444 \end{bmatrix}$$

and

$$R = \begin{bmatrix} 0.162 & 0.030 & 0.007 & 0.001 \\ 0.002 & 0.163 & 0.031 & 0.003 \\ 0.010 & 0.007 & 0.167 & 0.016 \\ 0.519 & 0.349 & 0.244 & 0.889 \end{bmatrix}.$$

(The last row of G does not add up to 1 because all round-offs to three decimals happen to be truncations on that row.) Some patterns emerge; for instance, we find from G that if the process starts from $(1, i)$ with $i = 1, 2$, or 3, it is most likely that the queue goes down to level 0 in the same phase, while if we start in phase 4, there is a significant probability that, when the queue has recovered from the arrival spurt, it has had the time to move to another phase.

A comparison of the rows of R indicates, not surprisingly, that the system spends more time in level 1 if it starts from level 0 in phase 4 than if it starts from one of the other three phases. The spectral radius of R is 0.896: this is greater than ρ , which makes one suspect that the queue is not quite as well behaved as the value of ρ seems to indicate. This is clearly shown through a comparison of the QBD to a simple queue with only one phase and arrival probability $p_\lambda^* = 0.75p_\lambda + 0.25p_\Lambda$, so that the two systems are equally loaded, in the long run. In the table below, m_1 and σ_1 are the mean and the standard deviation of the queue length for the QBD and m_2 and σ_2 correspond to the simple queue.

ρ	m_1	σ_1	m_2	σ_2
0.65	5.760	8.430	1.857	2.304

We also plot in Fig. 1 the distribution function of the queue size for the two systems. Both systems have the same probability of being empty but that is where the similarity stops, the QBD having a much longer tailed distribution.

Figure 1. Cumulative probability distribution of a queue in a random environment and of a simple queue, both with traffic coefficient $\rho = 0.65$.

FURTHER READING

The theory of QBDs is extensively covered in Neuts [24,25] and Latouche and Ramaswami [8]. Various extensions are covered there, such as M/G/1- and GI/M/1-type queues, QBDs on finitely many levels, and tree-like processes. Algorithmic issues are discussed in depth in Bini *et al.* [11], see also the article on Markov chains of the M/G/1 type [1]. Chapters on QBDs and their immediate extensions may be found in Asmussen [26], Breuer and Baum [27], Dshalalow [28], and Grassmann [29].

The methods from the theory of QBDs have seen their domain of application greatly extended over the year. One extension that we have mentioned in the introduction is that of level-dependent QBDs. These are processes for which the transition probabilities from level n may depend on n ; they are discussed in this encyclopedia and a good reference is Bright and Taylor [30].

Ramaswami [31] showed that the methods developed for QBDs might be applicable to fluid queues. Fluid queues are two-dimensional stochastic processes for which the level takes continuous values and evolve in a piecewise linear manner. The seminal paper of Ramaswami opened the way to many developments; recent papers on the subject are Ahn and Ramaswami [32], Bean *et al.* [33,34], and da Silva Soares and Latouche [35].

Recently, it has been shown that algorithm for the analysis of Markovian branching processes had much in common with

those for QBDs Bean *et al.* [36] and Hautphenne *et al.* [37].

LIFT-AND-PROJECT INEQUALITIES

QUENTIN LOUVEAUX
Montefiore Institute, University of
Liège, Liège, Belgium

Lift-and-project inequalities were proposed in the early 1990s as a way to strengthen the linear programming (LP) relaxation of a mixed-integer program (MIP). The initial idea was proposed by Lovász and Schrijver [1] when they obtained a strengthened formulation in an extended space by multiplying all constraints by all variables x_i and their complement and to project back to the initial space of variables. A similar but slightly different approach was then later proposed by Sherali and Adams [2]. In this survey, we follow the approach of Balas *et al.* [3] who showed that a simplified version of the Lovász–Schrijver reformulation keeps its main theoretical property. They also showed how the approach can successfully be incorporated in a branch-and-cut solver [4].

The general idea behind lift-and-project is the following: from an initial formulation, we can create a quadratic equivalent formulation by multiplying all inequalities by a binary variable x_j of the problem and its complement $(1 - x_j)$. If we linearize this formulation by introducing a variable $y_i := x_i x_j$, and replacing $x_j^2 = x_j$ (since $x_j \in \{0, 1\}$), we obtain an equivalent formulation in an extended space. This is the *lifting phase*. If we project this extended formulation onto the space of the initial variables, we obtain a strengthened formulation of the initial binary MIP. This is the *projecting phase*.

This article is further subdivided into two parts. The first section presents the lift-and-project technique and shows that it encodes a simple convexification process. We then show that this convexification process can be used sequentially in order to generate the convex hull of all feasible points. Lift-and-project inequalities can be related to other classes of inequalities. We also make this link in this section. The second section focuses on

the different ways to generate lift-and-project inequalities that cut off a fractional point, in particular, starting from the optimal simplex tableau of a linear relaxation. We also present some computational tests that have addressed the strength of the lift-and-project inequalities.

Two other references on the topic are the survey on cutting planes by Cornuéjols [5] and the survey on lift-and-project by Balas and Perregaard [6].

GENERAL THEORY

Before presenting the lift-and-project on its own, we first start with some basics about the projection of polyhedra since this is a building block of the lift-and-project technique.

Definition 1. Let $P \subseteq \mathbb{R}^{p+q}$ be a polyhedron where an element of P is denoted by $(x, y) \in P$, $x \in \mathbb{R}^p, y \in \mathbb{R}^q$. The projection of P on its first p coordinates is defined as

$$\text{proj}_x(P) = \{x \in \mathbb{R}^p \mid \exists y \in \mathbb{R}^q, \text{ with } (x, y) \in P\}.$$

The projection of a polyhedron can be computed using the following result.

Lemma 1. Let $P := \{(x, y) \in \mathbb{R}^{p+q} \mid Ax + Gy \geq b\}$. Let $\{u^t\}_{t \in t}$ be the list of extreme rays of $\{u \in \mathbb{R}^q \mid u^T G = 0, u \geq 0\}$. Then $\text{proj}_x(P) = \{x \in \mathbb{R}^p \mid (u^t)^T Ax \geq (u^t)^T b\}$.

Proof. See any textbook on linear and integer programming; for example, Refs 7–9.

We now turn to lift-and-project. We consider the mixed binary set $K_I = \{x \in \{0, 1\}^n \times \mathbb{R}_+^p \mid Ax \geq b\}$ with $A \in \mathbb{R}^{m \times (n+p)}$, $b \in \mathbb{R}^m$ and its linear relaxation $K = \{x \in \mathbb{R}_+^{n+p} \mid Ax \geq b\}$. We suppose that the constraints $x_i \geq 0, x_i \leq 1, i = 1, \dots, n$ are included in the description $Ax \geq b$. The lift-and-project technique is summarized in Table 1.

Table 1. Lift-and-Project Technique

Step 0	Select a binary variable $x_j, j = 1, \dots, n$.
Step 1	Multiply all constraints by x_j and $(1 - x_j)$ giving the quadratic system $Q_j(K) = \{x \in \mathbb{R}_+^{n+p} \mid x_j(Ax - b) \geq 0, (1 - x_j)(Ax - b) \geq 0\}$.
Step 2	Linearize $Q_j(K)$ by introducing a variable $y_i := x_i x_j, i \neq j$ and replacing x_j^2 by x_j . We obtain the polyhedron $M_j(K)$.
Step 3	Project $M_j(K)$ onto the space of the x -variables. The resulting polyhedron is $P_j(K)$.

Observation 1. $P_j(K) \subseteq K$.

Proof. If we sum up all inequalities defining $Q_j(K)$, we obtain $Ax \geq b$ and therefore summing up all inequalities defining $M_j(K)$, we also obtain $Ax \geq b$. It follows that any point $(x, y) \in M_j(K)$ must satisfy $Ax \geq b$. Hence, $P_j(K) \subseteq K$.

This shows that the lift-and-project technique produces a new valid formulation for the points in K_I . We can also observe that the only operation that takes care of the integrality of the variables is when we replace x_j^2 by x_j . This operation is only valid when $x_j \in \{0, 1\}$. The first theorem of this section is that the operation actually strengthens the formulation in the best possible way considering the fact that only the integrality of x_j is considered.

Theorem 1. $P_j(K) = \text{conv}\{(K \cap \{x_j = 0\}) \cup (K \cap \{x_j = 1\})\}$.

Proof. The proof is taken from Ref. 3.

- (i) $\text{conv}(K \cap \{x : x_j \in \{0, 1\}\}) \subseteq P_j(K)$. Let $\bar{x} \in K \cap \{x : x_j \in \{0, 1\}\}$. Define $\bar{y}_i = \bar{x}_i \bar{x}_j$ for $i \neq j$. Then $(\bar{x}, \bar{y}) \in M_j(K)$ and hence $\bar{x} \in P_j(K)$.
- (ii) $P_j(K) \subseteq \text{conv}(K \cap \{x : x_j \in \{0, 1\}\})$. Assume first $K \cap \{x : x_j = 0\} = \emptyset$. Then $x_j \geq \epsilon$ is valid for K for some $\epsilon > 0$. This implies that $(1 - x_j)(x_j - \epsilon) \geq 0$ is satisfied by any $x \in Q_j(K)$. Replacing x_j^2 by x_j , it follows that $x_j \geq 1$ is valid for $Q_j(K) \cap \{x : x_j^2 = x_j\}$ from which it follows that it is valid for $P_j(K)$. Hence, $P_j(K) \subseteq K \cap \{x : x_j = 1\}$. The case $K \cap \{x : x_j = 1\} = \emptyset$ is similar.

Assume now that $K \cap \{x : x_j = l\} \neq \emptyset, l = 0, 1$. Suppose $\alpha x \geq \beta$ is valid for $\text{conv}(K \cap \{x : x_j \in \{0, 1\}\})$. Since it is valid for $K \cap \{x : x_j = 0\}$, there exists $\lambda \geq 0$ such that $\alpha x + \lambda x_j \geq \beta$ is valid for K . Similarly, there exists $\mu \geq 0$ such that $\alpha x + \mu(1 - x_j) \geq \beta$. Multiplying these two inequalities by $(1 - x_j)$ and x_j respectively, we obtain that $(1 - x_j)(\alpha x + \lambda x_j - \beta) \geq 0$ and $x_j(\alpha x + \mu(1 - x_j) - \beta) \geq 0$ are valid for $Q_j(K)$. Adding these two inequalities yields $\alpha x + (\lambda + \mu)(x_j - x_j^2) - \beta \geq 0$. Hence, $\alpha x \geq \beta$ is valid for $Q_j(K) \cap \{x : x_j^2 = x_j\}$ and therefore it is valid for $P_j(K)$ too.

The nice feature about the lift-and-project technique is that it can be applied sequentially in order to generate $\text{conv}(K_I)$ in a finite number of steps.

Theorem 2. $P_n(P_{n-1}(\dots(P_1(K))\dots)) = \text{conv}(K_I)$.

Proof. The proof is taken from Ref. 5. We proceed by induction. Let $S_t := \{x \in \{0, 1\}^t \times \mathbb{R}^{n-t+p} : Ax \geq b\}$. We want to show that $P_t(\dots(P_1(K))\dots) = \text{conv}(S_t)$. This is true for $t = 1$ as was shown in Theorem 1. Thus, we consider $t \geq 2$ and suppose that it is true for $t - 1$. By the induction hypothesis, we have $P_t(\dots(P_1(K))\dots) = P_t(\text{conv}(S_{t-1}))$ and using again Theorem 1, we have

$$P_t(\dots(P_1(K))\dots) = \text{conv}((\text{conv}(S_{t-1}) \cap \{x_t = 0\}) \cup (\text{conv}(S_{t-1}) \cap \{x_t = 1\})). \quad (1)$$

For any set S that lies entirely on one side of a hyperplane H , we have that $\text{conv}(S) \cap H =$

$\text{conv}(S \cap H)$ [8]. We can therefore rewrite Equation (1) as

$$\begin{aligned} P_t(\dots(P_1(K)\dots) &= \text{conv}(\text{conv}(S_{t-1} \cap \{x_t = 0\}) \\ &\quad \cup (\text{conv}(S_{t-1} \cap \{x_t = 1\}))) \\ &= \text{conv}((S_{t-1} \cap \{x_t = 0\}) \\ &\quad \cup (S_{t-1} \cap \{x_t = 1\})) \\ &= \text{conv}(S_t). \end{aligned}$$

We see that if we apply the lift-and-project technique in sequence, we will eventually generate the integer hull of the initial set. On the other hand, if we apply the lift-and-project technique in “parallel,” we construct the so-called *lift-and-project closure*.

Definition 2. The lift-and-project closure is the set $\cap_{j=1}^n P_j(K)$.

Example. We now present a small example that illustrates the technique. Consider the simple two dimensional polyhedron

$$K = \{x \in \mathbb{R}^2 \mid 0 \leq x_1, x_1 \leq 1, 0 \leq x_2, x_2 \leq 1, \\ 5x_1 - 6x_2 \geq -3, x_1 + 6x_2 \geq 2\},$$

from which we are interested in the description of the integer hull (Fig. 1).

Step 0 We select $j = 1$.

Step 1 We multiply all inequalities by x_1 and $1 - x_1$. We obtain the quadratic system

$$\begin{aligned} Q_1(K) = \{x \in \mathbb{R}^2 \mid x_1^2 \geq 0, \quad x_1^2 \leq x_1, \\ x_1 - x_1^2 \geq 0, \quad x_1 - x_1^2 \leq 1 - x_1, \\ x_1x_2 \geq 0, \quad x_1x_2 \leq x_1, \\ x_2 - x_1x_2 \geq 0, \quad x_2 - x_1x_2 \leq 1 - x_1, \\ 5x_1^2 - 6x_1x_2 \geq -3x_1, \\ 5x_1 - 5x_1^2 - 6x_2 + 6x_1x_2 \geq -3 + 3x_1, \\ x_1^2 + 6x_1x_2 \geq 2x_1, \\ x_1 - x_1^2 + 6x_2 - 6x_1x_2 \geq 2 - 2x_1\}. \end{aligned}$$

Figure 1. The initial polyhedron K .

Step 2 We replace x_1^2 by x_1 and we linearize x_1x_2 by introducing the variable $y_2 := x_1x_2$. We obtain

$$\begin{aligned} L_1(K) = \{(x, y) \in \mathbb{R}^{2+1} \\ | \quad x_1 \geq 0, y_2 \geq 0, x_1 - y_2 \geq 0, \\ -x_1 \geq -1, x_2 - y_2 \geq 0, -x_1 - x_2 + y_2 \\ \geq -1 \\ 8x_1 - 6y_2 \geq 0, \quad -3x_1 - 6x_2 + 6y_2 \geq -3 \\ -x_1 + 6y_2 \geq 0, \quad 2x_1 + 6x_2 - 6y_2 \geq 2\}. \end{aligned}$$

Step 3 We now need to project out the y_2 variable. To do it, we may consider either a Fourier–Motzkin elimination or use Lemma 1. For the latter, we have to consider vectors $u \in \mathbb{R}_+^{10}$ that are extreme rays of

$$\begin{aligned} Q := \{u \in \mathbb{R}^{10} \mid u_2 - u_3 - u_5 + u_6 - 6u_7 \\ + 6u_8 + 6u_9 - 6u_{10} = 0, u_i \geq 0\}. \end{aligned}$$

The set Q has 18 extreme rays and considering some of them leads to redundant inequalities. If we consider $u_3^1 = 2, u_8^1 = \frac{1}{3}$, we obtain the inequality $x_1 - 2x_2 \geq -1$. Similarly, if we consider $u_8^2 = 1, u_{10}^2 = 1$, we obtain the inequality $x_1 \leq 1$. We can also finally obtain the inequalities $x_1 \geq 0$ and $x_1 + 6x_2 \geq 2$. All the other inequalities are redundant. The resulting polyhedron $P_1(K)$ is represented in Fig. 2. If we compute $P_2(P_1(K))$, we would obtain the integer hull of the initial polyhedron, namely, $P_2(P_1(K)) = \{(1, 1)\} = \text{conv}(K_I)$. The single point of K_I is shown in Fig. 2.

It is possible to make some connections between lift-and-project inequalities and

Figure 2. The polyhedron $P_1(K)$ after one iteration of the lift-and-project. After two iterations, we obtain the integer hull.

some other well-known classes of inequalities. Observe indeed that Theorem 1 has several implications that we summarize below.

Observation 2. The class of lift-and-project inequalities is a subset of

- disjunctive inequalities introduced by Balas [10] where the disjunction is $(x_j \leq 0) \vee (x_j \geq 1)$;
- Gomory mixed-integer cuts [11] or mixed-integer rounding [12];
- split cuts [13] where the corresponding split is $\{0 \leq x_j \leq 1\}$;
- intersection cuts [14].

GENERATING LIFT-AND-PROJECT CUTS

In this section, we consider the issue of optimizing a linear function over K_I . This is often done by considering the linear relaxation K and by finding cutting planes that cut off the optimal point of the linear relaxation. A natural question that we may ask is to find the best lift-and-project cut that cuts off an optimal vertex of the linear relaxation. This can be answered by solving a linear program as we explain below. Step 2 of the lift-and-project technique constructs the polyhedron

$$M_j(K) = \{x \in \mathbb{R}^{n+p} \mid Ay - bx_j \geq 0, \\ Ax + bx_j - Ay \geq b, y_j = x_j\}.$$

A simpler representation of M_j can be obtained by getting rid of the y_j variable.

If we denote by $\tilde{A}$ the matrix obtained by removing from A its j^{th} column A_j , we can rewrite $M_j(K)$ as

$$M_j(K) = \{x \in \mathbb{R}^{n+p}, y \in \mathbb{R}^{n+p-1} \mid \tilde{A}y + (A_j - b) \\ x_j \geq 0, Ax + (b - A_j)x_j - \tilde{A}y \geq b\}.$$

By renaming the matrices, we may write the set as

$$M_j(K) = \{x \in \mathbb{R}^{n+p}, y \in \mathbb{R}^{n+p-1} \mid \tilde{C}x + \tilde{A}y \geq 0, \\ \tilde{C}x - \tilde{A}y \geq b\}.$$

A valid lift-and-project inequality is a valid inequality for the set $\text{proj}_x M_j(K)$. It can be computed using Lemma 1 by considering the set $Q = \{(u, v) \in \mathbb{R}_+^m \times \mathbb{R}_+^m \mid u^T \tilde{A} - v^T \tilde{A} = 0, u, v \geq 0\}$. Therefore, an inequality is determined as $(u\tilde{C} + v\tilde{C})x \geq vb$ with $(u, v) \in Q$. If we want to cut off a specific point x^* , it can be modeled as the linear program

$$\begin{aligned} \max \quad & vb - (u\tilde{C} + v\tilde{C})x^*, \\ \text{s.t.} \quad & u^T \tilde{A} - v^T \tilde{A} = 0, \\ & u, v \in \mathbb{R}_+^m. \end{aligned}$$

This is the so-called cut-generating linear programming (henceforth denoted as CGLP) as opposed to the initial program denoted by LP) which needs an additional normalization constraint in order to be bounded. The CGLP has $2m$ variables and $n + p$ constraints and thus, has twice the size of the linear relaxation LP of the initial problem. It is therefore fairly impractical to solve it at each step in order to obtain just one cut. Balas and Perregaard [15] have however, shown that it is possible to mimic simplex pivots in CGLP by performing infeasible simplex pivots in LP. Actually, one simplex pivot in LP is not in one-to-one correspondence with a simplex pivot in CGLP but may correspond to many, often hundreds of (mostly degenerate) pivots in CGLP (see Ref. 16 for details and examples). More specifically, consider a row j in the optimal tableau LP

$$x_j = \bar{a}_{j0} - \sum_{l \in N} \bar{a}_{jl} x_l, \quad (2)$$

where N denotes the set of nonbasic variables. It can be shown that the Gomory mixed-integer cut generated from Equation (2) is a lift-and-project cut from $P_j(K)$. Therefore, there exists a basis of CGLP that corresponds to it. In other words, the optimal tableau of LP can be put in correspondence with a feasible basis of CGLP that represents a Gomory mixed-integer cut generated from Equation (2). Assume now that x_k enters the basis in row i ($i \neq j$) in LP. In the new basis, row j will become row j to which a multiple of row i is added, yielding a row of the type

$$x_j = \tilde{a}_{j0} - \sum_{l \in N} \tilde{a}_{jl} x_l. \quad (3)$$

The Gomory mixed-integer cut generated from Equation (3) is again a lift-and-project cut from $P_j(K)$ and corresponds to a basis of CGLP. Performing a pivot in LP therefore implicitly allows us to move to another basis in CGLP. The question is now how to choose the pivot a_{ik} in order to create a cut that is as strong as possible. There are two choices to be made: the row i and the column k . Improvement in the choice of row i is encoded through the reduced cost of u_i and v_i in CGLP but can be computed directly in LP. The choice of k can also be made from the data in LP in order to obtain a strong cut.

The size of CGLP is roughly twice that of LP and it is no wonder that one basis of CGLP is not in exact one-to-one correspondence to a basis of LP. It turns out that performing one pivot on LP often corresponds to several pivots in CGLP. Hence, it is much more efficient to generate lift-and-project cuts in LP as was also shown by computational evidence [15,16]. For more details on how to compute the reduced costs of u_i and v_i and how to select the variable x_k to pivot in, we refer to the papers by Balas and Perregaard [15] and by Balas and Bonami [16].

We also propose a geometric interpretation of why different bases of LP correspond to different lift-and-project cuts. Recall that a lift-and-project inequality can equivalently be seen as a disjunctive or a split cut using the disjunction $(x_j \leq 0) \vee (x_j \geq 1)$. These cuts can in turn, be interpreted as intersection cuts and are determined by the intersection

Figure 3. Geometric interpretation of lift-and-project cuts from feasible and infeasible bases.

of the rays of the bases with either $x_j = 0$ or $x_j = 1$. Figure 3 shows an example of two cuts determined from two different bases. The infeasible basis actually generates the stronger cut.

Balas and Jeroslow [17] have proposed a general method to strengthen valid inequalities of MIPs. This can also be applied in general to lift-and-project inequalities. Indeed, when we generate lift-and-project cuts, we only consider the integrality of x_j . We may also want to consider the integrality of other variables $x_i, i \neq j$. This may allow us to decrease their coefficients in the cut. This strengthening has the desirable property that it is extremely easy to incorporate once the CGLP has been solved.

Theorem 3. Consider the lift-and-project cut $\sum_{i=1}^{n+p} \alpha_i x_i \geq \beta$ obtained from the solution (u, v) of CGLP such that

$$\alpha_k = \begin{cases} \max(u^T A_k, v^T A_k) & k \neq j \\ \max(u^T A_j - u_0, v^T A_j + v_0) & k = j, \end{cases}$$

where A_k denotes the k^{th} column of A and $\beta = \min(u^T b, v^T b + u_0)$. Define $m_k = \frac{v^T A_k - u^T A_k}{u_0 + v_0}$ and

$$\bar{\alpha}_k = \begin{cases} \max(u^T A_k + u_0 \lceil m_k \rceil, v^T A_k - v_0 \lfloor m_k \rfloor) & k = 1, \dots, n, k \neq j \\ \max(u^T A_j - u_0, v^T A_j + v_0) & k = j, \\ \max(u^T A_k, v^T A_k) & k = n+1, \dots, p \end{cases}$$

and $\bar{\beta} = \min(u^T b, v^T b + v_0)$. Then, the inequality $\bar{\alpha}x \geq \bar{\beta}$ is valid for K_I and is called a strengthened lift-and-project cut.

Proof. See Ref. 17.

We close this survey article with some numerical tests that have been carried out using lift-and-project inequalities. There exist two commercial implementations of lift-and-project cuts (XPRESS and MOPS) and one open-source implementation Cgl-LandP [18] within the COIN-OR framework [19]. In an initial experiment, Bonami and Minoux [20] experimented on 35 mixed binary problems from the MIPLIB 3 library [21]. They have generated a series of lift-and-project inequalities in order to evaluate the gap closed by this family of cuts. Out of the 35 MIPLIB instances, they have found that the lift-and-project closure closes 37% of the integrality gap on average. This result needs to be moderated by the very large variance of the gap closed. Indeed, in 8 out of 35 instances, the gap closed is lower than 1%, whereas in 4 out of the 35 instances the gap closed is larger than 90%. By using strengthened lift-and-project cuts, the average gap closed increases by 8% to reach 45% gap closed on average. But again on 7 instances, the gap closed is lower than 1% and on 5 instances, the gap closed is larger than 90%.

More recently, Balas and Bonami [16] experimented on MIPLIB instances using the CglLandP cut generator within the COIN-OR framework. In this framework, the lift-and-project cuts are generated as a strengthening of the mixed-integer Gomory cuts by performing infeasible pivots in the optimal LP tableau. They compare the time needed to solve instances using either a cut-and-branch algorithm with mixed-integer Gomory cuts or a cut-and-branch algorithm with strengthened lift-and-project inequalities. For the easy instances, solved in less than 30 s, no major difference can be seen. However for the other instances, the time needed to solve the problems to optimality using the lift-and-project cuts can be drastically reduced compared to an implementation using Gomory cuts only. On average, the instances are solved in less than a third of the time when using the best implementation.

LIFTING TECHNIQUES FOR MIXED INTEGER PROGRAMMING

JEAN-PHILIPPE P. RICHARD
Department of Industrial and
Systems Engineering,
University of Florida,
Gainesville, Florida

INTRODUCTION

We consider mixed integer programs (MIPs) of the form

$$\max \left\{ f'x + g'y \mid Ax + By \leq d, \right. \\ \left. (x, y) \in \mathbb{Z}^m \times \mathbb{R}^n \right\}, \quad (1)$$

where $A \in \mathbb{Q}^{p \times m}$, $B \in \mathbb{Q}^{p \times n}$, $d \in \mathbb{Q}^p$, $f \in \mathbb{R}^m$, and $g \in \mathbb{R}^n$, and where bounds on the variables are treated as constraints. We denote the feasible region of problem (1) by $\mathcal{F}$. We also define $M = \{1, \dots, m\}$ and $N = \{1, \dots, n\}$. Given a set $M' \subseteq M$ (respectively, $N' \subseteq N$), we use the expression *variables in M'* (respectively, *in N'*) to describe the set of variables x_i for $i \in M'$ (respectively, y_j for $j \in N'$).

In both cutting-plane and branch-and-cut algorithms, an important practical problem is that of deriving strong valid inequalities for $\text{conv}(\mathcal{F})$. A key difficulty in the derivation of such inequalities is that the number of variables is large and therefore a direct geometric analysis of the polyhedral structure of $\text{conv}(\mathcal{F})$ is complex. Lifting is a method that can be used to circumvent this difficulty. It is the process by which a valid inequality for a restriction of the problem obtained by temporarily fixing variables to specific values (a *seed inequality*) is transformed into a valid inequality for the entire problem.

Example 1 [1]. Consider the mixed integer set

$$\tilde{\mathcal{F}} = \{(x_1, x_2, y_1) \in \mathbb{Z}^2 \times \mathbb{R} \mid x_1 + 2x_2 + 2y_1 \leq 3, \\ 0 \leq x_1 \leq 1, 0 \leq x_2 \leq 1, 0 \leq y_1 \leq 1\}.$$

The set $\tilde{\mathcal{F}}$ is presented in Fig. 1a and its convex hull is depicted in Fig. 1b. It can be verified that

$$\text{conv}(\tilde{\mathcal{F}}) = \{(x_1, x_2, y_1) \in \mathbb{Z}^2 \times \mathbb{R} \mid x_1 + 2x_2 \\ + 2y_1 \leq 3, x_2 + 2y_1 \leq 2, \\ 0 \leq x_1 \leq 1, 0 \leq x_2 \leq 1, y_1 \geq 0\}.$$

In particular, adding $x_2 + 2y_1 \leq 2$ to the inequalities defining $\tilde{\mathcal{F}}$ yields a linear description of $\text{conv}(\tilde{\mathcal{F}})$.

We now illustrate how lifting can be used to derive $x_2 + 2y_1 \leq 2$. First, we fix the variable y_1 to 1. The resulting set is $\tilde{\mathcal{F}}_{\{y_1=1\}} = \{(x_1, x_2, y_1) \in \{0, 1\}^2 \times [0, 1] \mid x_1 + 2x_2 \leq 1, y_1 = 1\}$. $\tilde{\mathcal{F}}_{\{y_1=1\}}$ is a slice of the feasible region. The seed inequality

$$x_2 \leq 0 \quad (2)$$

is valid for $\tilde{\mathcal{F}}_{\{y_1=1\}}$. The plane associated with inequality (2) is represented in Fig. 2a, where it can be seen that, although valid for $\tilde{\mathcal{F}}_{\{y_1=1\}}$, inequality (2) is not valid for $\tilde{\mathcal{F}}$. Lifting the variable y_1 is to determine a coefficient β for y_1 for which

$$x_2 + \beta(y_1 - 1) \leq 0 \quad (3)$$

is valid for $\tilde{\mathcal{F}}$. Note that the form $\beta(y_1 - 1)$ in inequality (3) is not innocuous as it guarantees that, when $y_1 = 1$, inequality (3) reduces to seed inequality (2). In this example, it is easy to verify that coefficients β , which ensure that inequality (3) is valid for $\tilde{\mathcal{F}}$ should be sufficiently large so as to guarantee that the point $(0, 1, \frac{1}{2})$ is feasible. This naturally leads to the conclusion that $1 + \beta(\frac{1}{2} - 1) \leq 0$, that is, $\beta \geq 2$. Because we are interested in generating the strongest possible inequality, we choose $\beta = 2$. Substituting β for 2 in inequality (2), we obtain $x_2 + 2y_1 \leq 2$, an inequality that defines a facet of $\text{conv}(\tilde{\mathcal{F}})$. The lifting coefficient β could also have been obtained algebraically as follows. First rewrite inequality (3) as $\beta(y_1 - 1) \leq -x_2$. Then observe that β is a

Figure 1. S and $\text{conv}(S)$ in Example 1.

valid lifting coefficient if

$$\beta \geq \max \left\{ \frac{-x_2}{y_1 - 1} \mid x_1 + 2x_2 + 2y_1 \leq 3, \right. \\ \left. x_1 \in \{0, 1\}, x_2 \in \{0, 1\} \text{ and } y_1 \in [0, 1] \right\}. \quad (4)$$

The optimal solution of this problem is $(x_1, x_2, y_1) = (0, 1, \frac{1}{2})$ yielding $\beta \geq 2$. For reasons that will become clear in the section titled “Computing and Recomputing the Lifting Function”, problem (4) is often reformulated as $\max \left\{ \frac{\tilde{\Psi}(2(y_1-1))}{y_1-1} \mid y_1 \in [0, 1] \right\}$, where $\tilde{\Psi}(z) = -\max\{x_2 \mid x_1 + 2x_2 \leq 1 - z, x_1 \in \{0, 1\}, x_2 \in \{0, 1\}\}$ is said to be the lifting function associated with inequality (2).

Example 1 also provides a geometric interpretation of lifting. First observe that the seed inequality (2) intersects the plane $y_1 = 1$ on the thick line represented in Fig. 2a. We refer to this line as *hinge*. Using this terminology, lifting corresponds to rotating the seed inequality plane around its hinge until it becomes valid for $\tilde{\mathcal{F}}$. Such rotation is not always possible as the following example illustrates.

Example 2 [1]. Consider the set $\tilde{\mathcal{F}}$ of Example 1. The inequality $x_1 + x_2 \leq 1$ is

valid for $\tilde{\mathcal{F}}_{\{y_1 = \frac{1}{2}\}}$, where y_1 is fixed to $\frac{1}{2}$.

To perform lifting, we must determine a coefficient β for which $x_1 + x_2 + \beta(y_1 - \frac{1}{2}) \leq 1$ is valid for $\tilde{\mathcal{F}}$. Because $(1, 1, 0)$ belongs to $\tilde{\mathcal{F}}$, it is clear that $\beta \geq 2$. Similarly since $(1, 0, 1)$ belongs to $\tilde{\mathcal{F}}$, $\beta \leq 0$. In other words, no matter how the plane $x_1 + x_2 = 1$ is rotated around its hinge, one of the two feasible points $(1, 0, 1)$ or $(1, 1, 0)$ will be cut off by the lifted inequality: lifting is impossible.

Geometrically, the reason that lifting is impossible in Example 2 is that there are feasible solutions on both sides of the plane $y_1 = \frac{1}{2}$. Further, the plane corresponding to the seed inequality must be rotated in one direction to satisfy the feasible points with $y_1 < \frac{1}{2}$, while it needs to be rotated in the other direction to satisfy the feasible points with $y_1 > \frac{1}{2}$. This does not happen in Example 1 since all feasible points are on one side of the plane $y_1 = 1$.

HISTORY OF LIFTING

The idea of extending linear functions from a linear subspace of a vector space to the vector space itself can be traced back to

Figure 2. Lifting seed inequality in Example 1.

Hahn–Banach’s extension theorem. For cutting planes in MIP, the ideas underlying lifting were first used by Gomory [2] for integer programs with feasible regions of the form:

$$\text{MG}(G, r) = \left\{ x \in \mathbb{Z}_+^{|G|} \mid \sum_{g \in G} g x_g \equiv r \pmod{1} \right\}, \quad (5)$$

where G is a finite group and $r \in G$. In particular, Gomory proved that strong valid inequalities for $\text{MG}(G, r)$ can be “lifted” into strong valid inequalities for $\text{MG}(G', r)$, where G' is a finite group that contains G as a subgroup [[2], Theorem 19].

In its current acceptance, lifting surfaced in the mid-1970s when it was used to derive facet-defining inequalities for various structured MIPs including knapsack problems, independence system problems, and vertex packing problems [3–8]. Lifting was recognized to be a generic computational tool to generate strong inequalities for 0-1 integer programs in Padberg [9]; see also Zemel [10]. For general unstructured IPs, lifting was formalized in Wolsey [11]. Further, Wolsey [12] introduced the concept of superadditive lifting that is now central to the practical use of lifting. The use of lifted inequalities

was first shown to be beneficial in solving unstructured 0-1 IPs in Crowder *et al.* [13]. Interest in lifting theory for unstructured MIPs was revived by Gu *et al.* [14], where superadditive conditions for efficient lifting were revisited and by Gu *et al.* [15], where the advantages of using lifting in software implementations were demonstrated. Although most early studies focused on lifting integer variables, the lifting of a single continuous variable in a knapsack constraint was studied in Marchand and Wolsey [16]. Sequential lifting for continuous variables was considered in Richard *et al.* [1,17]. Lifted inequalities have now been implemented in all leading commercial branch-and-cut software [18].

Although we center this presentation on lifting concepts that apply to all MIPs, lifting has been used to study many structured problems including 0-1 knapsack problems [5–7,19], variants of knapsack problems [1,16,17,20], knapsack models with side constraints [21–26], independence systems [4,27], set covering models [28], flow models [29,30], and the traveling salesman problem [31,32].

Finally, although initially devised for generating cutting planes in MIP, recent progress has been made in applying lifting to other settings. In particular, de Farias [33]

studied lifting for semicontinuous variables, Richard and Tawarmalani [34] extended lifting to general nonlinear settings, and Atamtürk and Narayanan [35] developed a more explicit lifting theory for conic MIPs. Specific applications of lifting for nonlinear problems also include de Farias *et al.* [36] and Lin and Vandenbussche [37].

FUNDAMENTALS OF LIFTING

We now give a general description of lifting in MIP adapting, restating and generalizing results in the papers [1,9,11,12,14,17,34,38].

Because lifting is typically performed in several rounds in which multiple variables can be lifted simultaneously, we rewrite problem (1) into a form that better captures the sequential nature of lifting. First, we divide the set of integer variables M into $(M_0, M_1, \dots, M_l)$ and the set of continuous variables N into $(N_0, N_1, \dots, N_l)$. We assume that the sets M_k are disjoint (but not necessarily nonempty) for $k = 0, \dots, l$ and that sets N_k are disjoint (but not necessarily nonempty) for $k = 0, \dots, l$. We also require that $|M_k| + |N_k| \geq 1$ for $k = 0, \dots, l$. We use the above notation to signify that, when deriving the lifted inequality, we first derive a seed inequality using only the variables in $M_0 \cup N_0$ and then perform l rounds of lifting, where the k th lifting round only involves variables in $M_k \cup N_k$. Second, we divide the set of constraints into $l + 2$ classes. The first class contains all constraints that relate variables belonging to different lifting rounds. The following $l + 1$ classes are composed of all constraints that relate variables belonging to a single lifting round. We mention that, in general, different *lifting orders*, that is, the way variables are arranged into the sets $M_0, M_1, \dots, M_l$ and $N_0, N_1, \dots, N_l$, result in different lifted inequalities; see the section titled “Superadditive Lifting” for an important exception.

Using the notation defined above, we rewrite problem (1) as

$$\mathcal{F} = \left\{ (x, y) \in \mathbb{Z}^m \times \mathbb{R}^n \mid \begin{array}{l} \sum_{k=0}^l \left(\sum_{i \in M_k} A_i^* x_i \right. \\ \quad \left. + \sum_{j \in N_k} B_j^* y_j \right) \leq d^* \\ \sum_{i \in M_k} A_i^k x_i + \sum_{j \in N_k} B_j^k y_j \\ \quad \leq d^k, \forall k = 0, \dots, l \end{array} \right\}.$$

In the above set, we denote by p^* the number of rows of the matrices A_i^* and B_j^* . In the remainder of the article, we often write x^k to represent the variables x_i for $i \in M_k$ and y^k to represent the variables y_j for $j \in N_k$. We also use the notation $m_k = |M_k|$ and $n_k = |N_k|$ for $k = 0, \dots, l$. We typically write $(x^0, x^1, \dots, x^l; y^0, y^1, \dots, y^l)$ to represent the variables x_i for $i \in M_0 \cup \dots \cup M_l$ and y_j for $j \in N_0 \cup \dots \cup N_l$. Finally, we define $\mathcal{P}^k := \left\{ (x^k, y^k) \in \mathbb{Z}^{m_k} \times \mathbb{R}^{n_k} \mid \sum_{i \in M_k} A_i^k x_i + \sum_{j \in N_k} B_j^k y_j \leq d^k \right\}$.

Next we describe the four key steps of the lifting process: (i) fixing variables, (ii) generating a seed inequality, (iii) computing/recomputing the lifting function, and (iv) deriving the lifting coefficients. Throughout the discussion, we use the following example to illustrate the steps of the lifting procedure.

Example 3. Consider an application where a supplier has a quantity C of a product that can be delivered to customers using n distribution channels. Channel i currently has a capacity of c_i units, but additional capacity can be installed in up to u_i discrete increments of Δ_i for $i = 0, \dots, n - 1$. The MIP formulation corresponding to this application is

$$\hat{\mathcal{F}} = \left\{ (x, y) \in \mathbb{Z}^n \times \mathbb{R}^n \mid \begin{array}{l} \sum_{j=0}^{n-1} y_j \leq C, 0 \leq y_j \\ \leq c_j + \Delta_j x_j, 0 \leq x_j \leq u_j, \forall j = 0, \dots, n - 1 \end{array} \right\}.$$

For this problem, it is clear that $A^* = (0, \dots, 0)$, $B^* = (1, \dots, 1)$, $d^* = C$, $A_j^j = (0, -\Delta_j, -1, 1)'$, $B_j^j = (-1, 1, 0, 0)'$ and $d^j = (0, c_j, 0, u_j)'$ for $j = 0, \dots, n - 1$.

Fixing Variables

The first step of the lifting process is to fix a subset of the variables to specific values. It is customary to fix these variables so that the problem restriction still contains some feasible solutions. Therefore, we assume that the fixing is consistent with a solution $(\bar{x}, \bar{y}) \in \mathcal{F}$ called *fixing point*, that is, variables x^k are

fixed to $\bar{x}^k$ and variables y^k are fixed to $\bar{y}^k$ for $k = 1, \dots, l$. The restriction of the set $\mathcal{F}$ we consider during the q th lifting round is

$$\mathcal{F}^q(\bar{x}, \bar{y}) = \{(x^0, \dots, x^q, y^0, \dots, y^q) \mid (x^0, \dots, x^q, \bar{x}^{q+1}, \dots, \bar{x}^l; y^0, \dots, y^q, \bar{y}^{q+1}, \dots, \bar{y}^l) \in \mathcal{F}\},$$

for $q = 0, \dots, l$. Similarly, we could have defined $\mathcal{F}^q(\bar{x}, \bar{y})$ explicitly as

$$\mathcal{F}^q(\bar{x}, \bar{y}) = \left\{ (x^0, \dots, x^q, y^0, \dots, y^q) \mid \begin{array}{l} \sum_{k=0}^q \left(\sum_{i \in M_k} A_i^* x_i \right. \\ \quad \left. + \sum_{j \in N_k} B_j^* y_j \right) \\ \leq d^*(q) \\ (x^k, y^k) \in \mathcal{P}^k, \\ \forall k = 0, \dots, q \end{array} \right\},$$

where $d^*(q) := d - \sum_{k=q+1}^l \left(\sum_{i \in M_k} A_i^* \bar{x}_i + \sum_{j \in N_k} B_j^* \bar{y}_j \right)$. Note that $\mathcal{F}^0(\bar{x}, \bar{y})$ contains only variables in M_0 and N_0 while $\mathcal{F}^l(\bar{x}, \bar{y}) = \mathcal{F}$.

Whether lifting is possible depends on both the seed inequality and the fixing point $(\bar{x}, \bar{y})$. In practice, $(\bar{x}, \bar{y})$ is often chosen to belong to the boundary of $\text{conv}(\mathcal{F})$, although this choice does not guarantee that lifting is possible; see Example 2. Another popular choice is to select the components of $(\bar{x}, \bar{y})$ to be upper or lower bounds on the corresponding variables. This fixing point ensures that lifting is possible, as the discussion following Example 2 suggests.

When $\mathcal{F}^q(\bar{x}, \bar{y})$ is not full-dimensional, its valid inequalities admit multiple equivalent representations. It then becomes typically difficult to determine what representation ultimately leads to strong lifted inequalities for $\text{conv}(\mathcal{F})$. For this reason, we will assume that lifting rounds and fixing points $(\bar{x}, \bar{y})$ are chosen in such a way that the sets $\mathcal{F}^q(\bar{x}, \bar{y})$ are full-dimensional. This assumption is consistent with the way inequalities are derived in practice.

Example 4. Consider an instance of the problem of Example 3 where $n = 5$, $C = 28$, $c_0 = c_1 = 3$, $c_i = i$ for $i = 2, \dots, 4$, $u_0 = u_1 = \infty$, $u_i = i - 1$ for $i = 2, \dots, 4$ and $\Delta_i = 2$ for $i = 0, \dots, 4$. The solution

$(\bar{x}; \bar{y}) = (0, 0, 1, 2, 3; 0, 3, 4, 7, 10)$ is feasible for $\hat{\mathcal{F}}$. We have

$$\hat{\mathcal{F}}^0(\bar{x}, \bar{y}) = \{(x_0, y_0) \in \mathbb{Z} \times \mathbb{R} \mid y_0 \leq 4, 0 \leq y_0 \leq 3 + 2x_0, x_0 \geq 0\}. \quad (6)$$

Generating a Seed Inequality

The second step of the lifting procedure is to derive a seed inequality

$$\sum_{i \in M_0} \alpha_i x_i + \sum_{j \in N_0} \beta_j y_j \leq \delta \quad (7)$$

that is valid for $\mathcal{F}^0(\bar{x}, \bar{y})$. Seed inequalities are often obtained through simple combinatorial, logical or even lifting arguments. Although the only strict requirement posed on inequality (7) is that it is valid for $\mathcal{F}^0(\bar{x}, \bar{y})$, it is typically chosen to define a face of large dimension of $\text{conv}(\mathcal{F}^0(\bar{x}, \bar{y}))$. This choice is made because strong inequalities remain strong if lifting is performed exactly; see Proposition 6 and ensuing paragraphs. We mention, however, that this choice does not guarantee that lifting is possible; see Example 2. In the remainder of this article, we assume that the face of $\text{conv}(\mathcal{F}^0(\bar{x}, \bar{y}))$ that inequality (7) defines is nonempty.

Example 5. Consider the set $\hat{\mathcal{F}}^0(\bar{x}, \bar{y})$ of Example 4. A linear inequality description of $\text{conv}(\hat{\mathcal{F}}^0(\bar{x}, \bar{y}))$ is given by $y_0 \leq 3 + x_0$, $y_0 \leq 4$, $y_0 \geq 0$, and $x_0 \geq 0$. We therefore choose our seed inequality to be

$$y_0 \leq 3 + x_0. \quad (8)$$

The above first two steps of lifting are performed once. The following two will be repeated l times.

Computing and Recomputing the Lifting Function

Because lifting is a sequential process, we assume here that we already have lifted variables in $M_1 \cup N_1, M_2 \cup N_2, \dots, M_{q-1} \cup N_{q-1}$

for some $q \in \{1, \dots, l\}$ and have generated the lifted seed inequality

$$\sum_{i \in M_0} \alpha_i x_i + \sum_{j \in N_0} \beta_j y_j + \sum_{k=1}^{q-1} \left(\sum_{i \in M_k} \alpha_i (x_i - \bar{x}_i) + \sum_{j \in N_k} \beta_j (y_j - \bar{y}_j) \right) \leq \delta. \quad (9)$$

We assume that lifting was possible in each of these steps and that inequality (9) is valid for $\mathcal{F}^{q-1}(\bar{x}, \bar{y})$. We are interested in lifting variables x_i for $i \in M_q$ and y_j for $j \in N_q$ into inequality (9), that is, we are interested in finding coefficients α_i for $i \in M_q$ and β_j for $j \in N_q$ for which

$$\sum_{i \in M_0} \alpha_i x_i + \sum_{j \in N_0} \beta_j y_j + \sum_{k=1}^q \left(\sum_{i \in M_k} \alpha_i (x_i - \bar{x}_i) + \sum_{j \in N_k} \beta_j (y_j - \bar{y}_j) \right) \leq \delta$$

is valid for $\mathcal{F}^q(\bar{x}, \bar{y})$. To this end, we introduce the q th lifting function $\Psi^q : \mathbb{R}^{p^*} \rightarrow \mathbb{R}$ as

$$\begin{aligned} \Psi^q(z) = & \delta \\ & - \max \left\{ \sum_{i \in M_0} \alpha_i x_i + \sum_{j \in N_0} \beta_j y_j \right. \\ & \left. + \sum_{k=1}^{q-1} \left(\sum_{i \in M_k} \alpha_i (x_i - \bar{x}_i) + \sum_{j \in N_k} \beta_j (y_j - \bar{y}_j) \right) \right\} \\ \text{s.t. } & \sum_{k=0}^{q-1} \left(\sum_{i \in M_k} A_i^* x_i + \sum_{j \in N_k} B_j^* y_j \right) \\ & + \sum_{k=q}^l \left(\sum_{i \in M_k} A_i^* \bar{x}_i + \sum_{j \in N_k} B_j^* \bar{y}_j \right) \leq d - z \\ & (x^k, y^k) \in \mathcal{P}^k, \forall k = 0, \dots, q-1, \end{aligned}$$

where we set $\Psi^q(z) = \infty$ if the optimization problem is infeasible. This definition is a direct generalization of the function we introduced in Example 1 to reformulate problem (4). For each vector $z \in \mathbb{R}^{p^*}$, the lifting function represents the amount of slack there is in inequality (9) when the variables in

$M_0, \dots, M_{q-1}$ and $N_0, \dots, N_{q-1}$ are allowed to contribute $d^*(q-1) - z$ to the left-hand side of the problem constraints.

Example 6. The lifting function associated with inequality (8) is defined as $\hat{\Psi}^1(z) = 3 - \max\{y_0 - x_0 \mid y_0 \leq 4 - z, 0 \leq y_0 \leq 3 + 2x_0, x_0 \in \mathbb{Z}_+\}$ and is represented in Fig. 3a. It can be verified that $\hat{\Psi}^1(z) = \max\{\lfloor \frac{z}{2} \rfloor, z - \lceil \frac{z}{2} \rceil\}$ when $z \leq 1$, $\hat{\Psi}^1(z) = z - 1$ when $1 \leq z \leq 4$ and $\hat{\Psi}^1(z) = \infty$ when $z > 4$.

Because inequality (9) is valid for $\mathcal{F}^{q-1}(\bar{x}, \bar{y})$, $\Psi^q(z) \geq 0$ for $z \in \mathbb{R}_+^{p^*}$ and $\Psi^q(0) = 0$ if inequality (9) defines a nonempty face of $\text{conv}(\mathcal{F}^{q-1}(\bar{x}, \bar{y}))$. Further, using the fact that the feasible set of the problem defining $\Psi^q(z)$ is a subset of those defining $\Psi^{q+1}(z)$ and $\Psi^q(z - \epsilon)$ for $\epsilon \in \mathbb{R}_+^{p^*}$, $\Psi^q(z)$ is nonincreasing in q and nondecreasing in z .

Proposition 1. For $q \in \{1, \dots, l\}$, $\Psi^q(z) \geq 0$ for $z \in \mathbb{R}_+^{p^*}$. Further, (i) for $q_1, q_2 \in \{1, \dots, l\}$ with $q_1 \leq q_2$, we have $\Psi^{q_1}(z) \geq \Psi^{q_2}(z)$ for all $z \in \mathbb{R}^{p^*}$ and (ii) for $z_1, z_2 \in \mathbb{R}^{p^*}$ with $z_1 \leq z_2$, we have $\Psi^q(z_1) \leq \Psi^q(z_2)$ for $q = 1, \dots, l$.

To conclude our discussion of lifting functions, we mention that if inequality (9) is valid for $\mathcal{F}^{q-1}(\bar{x}, \bar{y})$, then

$$\begin{aligned} & \sum_{i \in M_0} \alpha_i x_i + \sum_{j \in N_0} \beta_j y_j + \sum_{k=1}^{q-1} \left(\sum_{i \in M_k} \alpha_i (x_i - \bar{x}_i) \right. \\ & \quad \left. + \sum_{j \in N_k} \beta_j (y_j - \bar{y}_j) \right) \\ & \quad + \Psi^q \left(\sum_{k=q}^r \left(\sum_{i \in M_k} A_i^* (x_i - \bar{x}_i) \right. \right. \\ & \quad \left. \left. + \sum_{j \in N_k} B_j^* (y_j - \bar{y}_j) \right) \right) \leq \delta \quad (10) \end{aligned}$$

is a valid nonlinear inequality for $\mathcal{F}^r(\bar{x}, \bar{y})$ for all $r = q, \dots, l$.

Figure 3. Lifting functions and problems for Example 6.

Deriving Lifting Coefficients

In order for coefficients α_i for $i \in M_q$ and $\beta_j \in N_q$ to yield a valid inequality for $\mathcal{F}^q(\bar{x}, \bar{y})$, these coefficients must be chosen so that

$$\sum_{i \in M_0} \alpha_i x_i + \sum_{j \in N_0} \beta_j y_j + \sum_{k=1}^q \left(\sum_{i \in M_k} \alpha_i (x_i - \bar{x}_i) + \sum_{j \in N_k} \beta_j (y_j - \bar{y}_j) \right) \leq \delta \quad (11)$$

is satisfied by all points $(x^0, \dots, x^q; y^0, \dots, y^q)$ in $\mathcal{F}^q(\bar{x}, \bar{y})$. This requirement can also be expressed as

$$\begin{aligned} & \sum_{i \in M_q} \alpha_i (x_i - \bar{x}_i) + \sum_{j \in N_q} \beta_j (y_j - \bar{y}_j) \\ & \leq \Psi^q \left(\sum_{i \in M_q} A_i^* (x_i - \bar{x}_i) + \sum_{j \in N_q} B_j^* (y_j - \bar{y}_j) \right) \end{aligned} \quad (12)$$

for all $(x^q, y^q) \in \mathcal{P}^q$. Condition (12) only involves the variables (x^q, y^q) being lifted.

Geometrically, condition (12) requires that the hyperplane with normal vector (α^q, β^q) created in the space of lifted variables (x^q, y^q) lower approximates $\Psi^q \left(\sum_{i \in M_q} A_i^* (x_i - \bar{x}_i) + \sum_{j \in N_q} B_j^* (y_j - \bar{y}_j) \right)$ over $\mathcal{P}^q$. In order to obtain a strong inequality, we should search for coefficients (α^q, β^q) that define a hyperplane that supports this function at as many affinely independent points as possible. It is clear that in general, several choices for (α^q, β^q) are admissible. Because we have established in Proposition 1 that lifting functions Ψ^q are nonincreasing in q , conditions (12) also imply that if we delay the lifting of a variable from one round to the next, its lifting coefficients will be no stronger than those it would have received if it had been lifted earlier.

Example 7. To compute lifting coefficients for (x_1, y_1) we first display the function $\hat{\Psi}^1(y_1 - 3)$ over part of $\hat{\mathcal{P}}^1 = \{(x_1, y_1) \in \mathbb{Z}_+ \times \mathbb{R}_+ \mid y_1 \leq 3 + 2x_1\}$ in Fig. 3b, where the horizontal axes are x_1 and $y_1 - 3$. We must determine coefficients α_1, β_1 for which the plane $\alpha_1 x_1 + \beta_1 (y_1 - 3)$

underestimates $\hat{\Psi}^1(y_1 - 3)$ over $\hat{\mathcal{P}}^1$. Choosing $\alpha_1 = -1$, $\beta_1 = 1$ yields such a plane that passes through the points $(0, 3, 0)$, $(0, 2, -1)$ and $(1, 4, 0)$. This plane is represented in Fig. 3c where the horizontal axes are x_1 and y_1 . The lifted inequality is therefore

$$y_0 + y_1 \leq 6 + x_0 + x_1. \quad (13)$$

We discussed in the section titled “Computing and Recomputing the Lifting Function” that lifting functions can be used to construct valid nonlinear inequalities of the form (10). Requirement (12) can therefore also be interpreted as a condition that allows the linearization of the nonlinear inequality (10) when $r = q$ into valid inequality (11).

PRACTICAL AND COMPUTATIONAL ASPECTS OF LIFTING

The main computational burdens associated with lifting are the computation of $\Psi^q(z)$ for $q = 1, \dots, l$ and the derivation of the associated lifting coefficients. We address these computational aspects next.

About Lifting Functions

Computing Lifting Functions. We introduced lifting functions as a medium by which valid lifting coefficients could be obtained through the study of system (12). We mention first that, although convenient for presentation purposes, the computation of lifting functions is not always necessary in lifting. For instance, assume that binary variable x_r is being lifted as a single variable in the q th round and that $\bar{x}_r = 0$. Then condition (12) reduces to $\alpha_r \leq \Psi^q(A_r)$, a system that can be set up with the solution of the single MIP defining $\Psi^q(A_r)$. In such an instance, computing the lifting function over a large range of z values might neither be necessary nor computationally advantageous. This observation carries over to situations where $\mathcal{P}^q$ is a simple set.

When $\mathcal{P}^q$ is complex, it is common to compute the value of $\Psi^q(z)$ over a subset of $\mathbb{R}^p$ that contains $\left\{ \sum_{i \in M_q} A_i^*(x_i - \bar{x}_i) + \sum_{j \in N_q} B_j^*(y_j - \bar{y}_j) \mid (x^q, y^q) \in \mathcal{P}^q \right\}$

(or the smaller subset that will be described in the section titled “General Techniques for Deriving Lifting Coefficients”). In specific situations, lifting functions can be obtained in closed form either because the seed inequality has few variables or because the structure of the seed inequality is simple; see Marchand and Wolsey [16] for an example. However, since lifting functions may change with every set of variables that is reintroduced, lifting functions Ψ^q are typically not easy to describe in closed form even if Ψ^1 is known in closed form.

A way to derive (and store) lifting functions is to use dynamic programming (DP):

$$\begin{aligned} \Psi^{q+1}(z) = \min_{(x^q, y^q) \in \mathcal{P}^q} & \left\{ \Psi^q \left(z + \sum_{i \in M_q} A_i^*(x_i - \bar{x}_i) \right. \right. \\ & + \sum_{j \in N_q} B_j^*(y_j - \bar{y}_j) \left. \right) - \sum_{i \in M_q} \alpha_i(x_i - \bar{x}_i) \\ & \left. - \sum_{j \in N_q} \beta_j(y_j - \bar{y}_j) \right\}. \end{aligned} \quad (14)$$

When the number of constraints defining $\mathcal{F}$ is small and the coefficients of variables are not large, the recursion (14) or variants can sometimes be used to efficiently obtain the lifting function $\Psi^{q+1}(z)$ from $\Psi^q(z)$. This is, for example, the case when lifting cover inequalities for the 0-1 knapsack polytope [[40], Section II.2.2]. However, in most situations, recurrence (14) does not yield an efficient algorithm for computing lifting functions as its state space might be infinite and even when it is not, a pseudopolynomial amount of computation is typically required to obtain $\Psi^{q+1}(z)$ from $\Psi^q(z)$.

Example 8. For Example 7, we compute

$$\begin{aligned} \hat{\Psi}^2(z) = \min & \{ \hat{\Psi}^1(z + (y_1 - 3)) + x_1 - (y_1 - 3) \mid \\ & 0 \leq y_1 \leq 3 + 2x_1, x_1 \geq 0, x_1 \in \mathbb{Z}, y_1 \in \mathbb{R} \}, \end{aligned}$$

that is, $\hat{\Psi}^2(z) = \max\{\lfloor \frac{z}{2} \rfloor, z - \lceil \frac{z}{2} \rceil\}$ when $z \leq 1$, $\hat{\Psi}^2(z) = z - 1$ when $1 \leq z \leq 7$ and $\hat{\Psi}^2(z) = \infty$ when $z > 7$.

Because computing lifting functions can be time-consuming, it is sometimes advantageous to compute their values approximately. In particular, as long as a lower approximation $\psi^q(z)$ of $\Psi^q(z)$ is obtained, the lifting coefficients derived from the analysis of condition (12), where Ψ^q is replaced with $\psi^q(z)$ will be valid. An option to obtain $\psi^q(z)$ is to solve the linear programming (LP) relaxation of $\Psi^q(z)$ and round the resulting value up if the objective value is known to be integral. Similar ideas were shown to be computationally useful in Crowder *et al.* [13] and Gu *et al.* [15] in the case of 0-1 knapsack sets. LP-based lifting has also been studied in Dey and Richard [41].

Superadditive Lifting. The main computational difficulty with lifting functions is that $\Psi^{q+1}(z)$ and $\Psi^q(z)$ are typically different. For practical purposes, it is therefore interesting to identify conditions under which $\Psi^1(z) = \Psi^2(z) = \dots = \Psi^l(z)$ for all vectors z in an appropriately chosen subset S of $\text{dom}(\Psi^1(z))$. Such conditions were discovered by Wolsey [12]; see also Gu *et al.* [14]. To motivate their introduction, we consider the case where we lift a single binary variable x_r that was fixed at 0 in the q th round of lifting. In this case, the DP recursion (14) takes the form

$$\begin{aligned}\Psi^{q+1}(z) &= \min_{x_r \in \{0,1\}} \{ \Psi^q(z + A_r^* x_r) - \Psi^q(A_r^* x_r) \} \\ &= \min \{ \Psi^q(z), \Psi^q(z + A_r^*) - \Psi^q(A_r^*) \},\end{aligned}$$

since it follows from our discussion in the section titled “Computing Lifting Functions” that $\alpha_r = \Psi(A_r^*)$ is a strong valid lifting coefficient for x_r when $\Psi(A_r^*) < \infty$. In order for $\Psi^{q+1}(z)$ to be equal to $\Psi^q(z)$, it suffices to require that $\Psi^q(z) \leq \Psi^q(z + A_r^*) - \Psi^q(A_r^*)$ for all vectors z . More generally, given a function $\phi : \mathbb{R}^n \mapsto \mathbb{R} \cup \{\pm\infty\}$, we say that ϕ is (S_1, S_2) -superadditive if $\phi(A) + \phi(B) \leq \phi(A + B)$ for all $A \in S_1$, and $B \in S_2$. When $S_1 = S_2$, we say that ϕ is superadditive over S_1 .

Proposition 2. *Define*

$$\begin{aligned}T^q &:= \left\{ \sum_{i \in M_q} A_i^*(x_i - \bar{x}_i) + \sum_{j \in N_q} B_j^*(y_j - \bar{y}_j) \mid \right. \\ &\quad \left. (x^q, y^q) \in \mathcal{P}^q \right\}.\end{aligned}$$

Assume that (i) $T^q \subseteq \text{dom}(\Psi^q)$, (ii) $\Psi^q(z)$ is (T^q, S) -superadditive, and (iii) lifting coefficients (α^q, β^q) for variables (x^q, y^q) exist that satisfy condition (12). Then $\Psi^{q+1}(z) = \Psi^q(z)$ for all $z \in S$.

The proof of Proposition 2 uses recursion (14) to argue that $\Psi^{q+1}(z) \geq \Psi^q(z)$ for all $z \in S$ and Proposition 1 to show that equality holds. Applying Proposition 2 sequentially, we conclude that lifting coefficients for all lifting rounds can be obtained from Ψ^1 if Ψ^1 is superadditive over an appropriate domain.

Proposition 3. Assume that (i) $T^q \subseteq \text{dom}(\Psi^1)$ for all $q = 1, \dots, l$, (ii) Ψ^1 is $(T_q, T_{q+1} + \dots + T_l)$ -superadditive for all $q = 1, \dots, l$ and (iii) lifting coefficients (α^q, β^q) , for variables (x^q, y^q) exist that satisfy condition (12) in which Ψ^q is replaced with Ψ^1 . Then

$$\begin{aligned}\sum_{i \in M_0} \alpha_i x_i + \sum_{j \in N_0} \beta_j y_j + \sum_{k=1}^l \left(\sum_{i \in M_k} \alpha_i (x_i - \bar{x}_i) \right. \\ \left. + \sum_{j \in N_k} \beta_j (y_j - \bar{y}_j) \right) \leq \delta \quad (15)\end{aligned}$$

is a valid inequality for $\text{conv}(\mathcal{F})$.

Proposition 3 can be proven by induction showing that $\Psi^q(z) = \Psi^1(z)$ for all z in $T_q + \dots + T_l$ using Proposition 2. Another way of deriving the result follows by realizing that assumption (ii) implies that

$$\begin{aligned}\sum_{q=1}^l \Psi^1 \left(\sum_{i \in M_q} A_i^*(x_i - \bar{x}_i) + \sum_{j \in N_q} B_j^*(y_j - \bar{y}_j) \right) \\ \leq \Psi^1 \left(\sum_{q=1}^l \left(\sum_{i \in M_q} A_i^*(x_i - \bar{x}_i) \right. \right. \\ \left. \left. + \sum_{j \in N_q} B_j^*(y_j - \bar{y}_j) \right) \right). \quad (16)\end{aligned}$$

Using this observation in inequality (10), where $i = 1$, we obtain the following relaxed

nonlinear inequality

$$\sum_{i \in M_0} \alpha_i x_i + \sum_{j \in N_0} \beta_j y_j + \sum_{q=1}^l \times \Psi^1 \left(\sum_{i \in M_q} A_i^*(x_i - \bar{x}_i) + \sum_{j \in N_q} B_j^*(y_j - \bar{y}_j) \right) \leq \delta$$

that can be linearized into inequality (15) using assumptions (i) and (iii).

In practice, Proposition 3 is often applied by selecting S_1 and S_2 to be small supersets of the sets $\mathcal{T}^1 \cup \dots \cup \mathcal{T}^l$ and $\mathcal{T}^1 + \dots + \mathcal{T}^l$ and then by verifying that Ψ^1 is (S_1, S_2) -superadditive so that assumption (ii) in Proposition 3 is naturally satisfied. In such a situation, the same lifted inequalities will be obtained no matter how lifting rounds are permuted and so lifting is said to be *sequence independent*. This is unlike what happens in general where the values that lifting coefficients take depend on their lifting round: better lifting coefficients are obtained in earlier rounds.

Superadditive conditions typically allow the derivation of strong closed-form inequalities. For instance, sequence-independent lifting has been used by Marchand and Wolsey [16] to derive facet-defining inequalities for a family of mixed integer knapsack sets and by Gu *et al.* [30] to derive valid inequalities for fixed-charge flow models. This concept admits generalizations in nonlinear programming [34,35].

Proving that the given functions are superadditive is cumbersome. However, several generic families of functions have been shown to be superadditive [14,20]. Necessary/sufficient conditions for certain univariate functions to be superadditive are given in Richard [42] and Richard *et al.* [43].

Example 9. The lifting function $\hat{\Psi}^2$ of Example 8 is superadditive over $S = \mathbb{N}^-$. Further $\hat{\mathcal{T}}^i = \{(y_i - (3i - 2)) \mid 0 \leq y_i \leq i + 2x_i, x_i \in \{0, \dots, i - 1\}\} = [-3i + 2, 0]$, for $i = 2, 3, 4$. Since $\hat{\mathcal{T}}^i \subseteq S$ for $i = 2, 3, 4$ and $\hat{\mathcal{T}}^2 + \hat{\mathcal{T}}^3 + \hat{\mathcal{T}}^4 \subseteq S$, we conclude from Proposition 2 that $\hat{\Psi}^i(z) = \hat{\Psi}^2(z)$ for all $z \in \hat{\mathcal{T}}^i$ when $i = 2, 3, 4$ if (α_2, β_2) and (α_3, β_3) exist

that satisfy condition (12) in which Ψ^q is replaced with $\hat{\Psi}^2$.

Approximate Lifting. When lifting functions are not superadditive, lifting can quickly become computationally expensive as it requires lifting functions to be recomputed. Superadditive conditions can be used to alleviate some of these computational difficulties if it is admissible to sacrifice some strength in the lifted inequality.

Proposition 4. Assume that (i) $\phi(z) \leq \Psi^1(z)$ for all $z \in \mathcal{T}_1 + \dots + \mathcal{T}_l$, (ii) $\mathcal{T}^q \subseteq \text{dom}(\phi)$ for all $q = 1, \dots, l$, (iii) ϕ is $(\mathcal{T}_q, \mathcal{T}_{q+1} + \dots + \mathcal{T}_l)$ -superadditive for all $q = 1, \dots, l$ and (iv) lifting coefficients (α^q, β^q) for variables (x^q, y^q) exist that satisfy condition (12) in which Ψ^q is replaced with ϕ . Then inequality (15) is a valid inequality for $\text{conv}(\mathcal{F})$.

The proof of Proposition 4 can be obtained similarly to that of Proposition 3 by showing by induction that $\Psi^q(z) \geq \phi(z)$ for all z in $\mathcal{T}_q + \dots + \mathcal{T}_l$ (note here that Ψ^q is the lifting function of the inequality obtained by using ϕ in the derivation of lifting coefficients (α_k, β_k) for $k = 1, \dots, q - 1$). The result can also be obtained by lower bounding Ψ^1 by ϕ in inequality (10), where $i = 1$ before using the superadditivity of ϕ in a manner similar to inequality (16) to obtain

$$\sum_{i \in M_0} \alpha_i x_i + \sum_{j \in N_0} \beta_j y_j + \sum_{q=1}^l \phi \left(\sum_{i \in M_q} A_i^*(x_i - \bar{x}_i) + \sum_{j \in N_q} B_j^*(y_j - \bar{y}_j) \right) \leq \delta,$$

which can then be linearized using assumptions (ii) and (iv).

Deriving a superadditive approximation of a given lifting function can be difficult. However, for univariate functions, Gu *et al.* [14] proved that such a superadditive approximation exists. Approximate superadditive lifting has been used in various settings where deriving closed-form facet-defining inequalities is difficult. It was first proposed by Gu *et al.* [14] for the cover inequality in 0-1

knapsack polytopes where desirable characteristics of superadditive approximations are described [20,44,45]. We refer the reader to papers [14,26,30] for discussions and applications.

About Lifting Coefficients

General Techniques for Deriving Lifting Coefficients. The problem of determining lifting coefficients is that of finding (α^q, β^q) that satisfy condition (12). In particular, condition (12) imposes a relation between (α^q, β^q) for each point of $\mathcal{P}^q$. Since there can be infinitely many of them, such a derivation is not always simple. One possible way of reducing the number of conditions to consider comes from observing that, in order to ensure that an inequality is valid for $\text{conv}(\mathcal{F}^q(\bar{x}, \bar{y}))$, it suffices to prove that it is satisfied at its extreme points and that its homogeneous counterpart is satisfied at its extreme rays. In particular, when $\text{conv}(\mathcal{F}^q(\bar{x}, \bar{y}))$ is bounded, it suffices to consider condition (12) for those points $(\tilde{x}^q, \tilde{y}^q)$ for which there exists an extreme point of $\text{conv}(\mathcal{F}^q(\bar{x}, \bar{y}))$ of the form $(x^0, \dots, x^{q-1}, \tilde{x}^q; y^0, \dots, y^{q-1}, \tilde{y}^q)$. Since there are finitely many such points, condition (12) defines a polyhedron Λ^q in the space of (α^q, β^q) variables. If Λ^q is empty, lifting is impossible. Otherwise, extreme points of Λ^q yield strong lifted inequalities; see the section titled “On the Strength of the Lifting Procedure”. Therefore, the derivation of lifting coefficients often reduces to finding extreme points of Λ^q . Since describing all extreme points of $\text{conv}(\mathcal{F}^q(\bar{x}, \bar{y}))$ can be difficult, it is common to restrict the number of variables in (M^q, N^q) to be small so that Λ^q is a small-dimensional polyhedron.

Lifting Coefficients from Superadditive Lifting Functions. We mentioned in the section titled “Superadditive Lifting” that lifting exhibits sequence-independent properties when lifting functions are superadditive. Another advantage occurs when deriving lifting coefficients. To illustrate this advantage, assume for the sake of simplicity that there are only integer variables in the definition of $\mathcal{F}$ and that $x^q \geq \bar{x}^q$ for all $x^q \in \mathcal{P}^q$. In this case, if Ψ^q is superadditive

over an appropriate domain, we can write

$$\sum_{i \in M_q} \Psi^q(A_i^*)(x_i - \bar{x}_i) \leq \Psi^q \left(\sum_{i \in M_q} A_i^*(x_i - \bar{x}_i) \right), \quad (17)$$

showing that $\alpha_i = \Psi^q(A_i^*)$ are coefficients that satisfy condition (12). Similarly, the following result can be established, where we make use of Proposition 7.2 of Section II.1.7 of Nemhauser and Wolsey [40].

Proposition 5. *Let $\mathcal{H}^q$ be a mixed integer set of the form $\{(x^q, y^q) \in \mathbb{Z}^{m_q} \times \mathbb{R}^{n_q} \mid l_i \leq x_i \leq u_i \forall i \in M_q \text{ and } \bar{l}_j \leq y_j \leq \bar{u}_j \forall j \in N_q\}$ (where $l_i, u_i, \bar{l}_j$, and $\bar{u}_j$ are possibly infinite) that is such that $\mathcal{P}^q \subseteq \mathcal{H}^q$. Assume that Ψ^q is superadditive over*

$$\mathcal{W}^q := \left\{ \sum_{i \in M_q} A_i^*(x_i - \bar{x}_i) + \sum_{j \in N_q} B_j^*(y_j - \bar{y}_j) \mid (x^q, y^q) \in \mathcal{H}^q \right\}$$

and that Ψ^q has directional derivatives in the directions B_j^* and $-B_j^*$ for all $j \in N_q$. Assume also that (α^q, β^q) is a feasible solution to the system

$$\alpha_i \leq \Psi^q(A_i^*) \quad \forall i \in M_q$$

for which $\exists (x^q, y^q) \in \mathcal{P}^q$ with $x_i > \bar{x}_i$ (18)

$$\alpha_i \geq -\Psi^q(-A_i^*) \quad \forall i \in M_q$$

for which $\exists (x^q, y^q) \in \mathcal{P}^q$ with $x_i < \bar{x}_i$ (19)

$$\beta_j \leq \lim_{\lambda \rightarrow 0^+} \frac{\Psi^q(\lambda B_j^*)}{\lambda} \quad \forall j \in N_q$$

for which $\exists (x^q, y^q) \in \mathcal{P}^q$ with $y_j > \bar{y}_j$ (20)

$$\beta_j \geq -\lim_{\lambda \rightarrow 0^+} \frac{\Psi^q(-\lambda B_j^*)}{\lambda} \quad \forall j \in N_q$$

for which $\exists (x^q, y^q) \in \mathcal{P}^q$ with $y_j < \bar{y}_j$, (21)

then (α^q, β^q) satisfies condition (12).

In Proposition 5, $\mathcal{W}^q$ is a superset of $\mathcal{T}^q$ that is typically larger than necessary. Superadditivity of Ψ^q over $\mathcal{W}^q$ allows a derivation of the result in a manner similar to inequality (17).

Further, if Ψ^1 is superadditive over an appropriate subset of $\text{dom}(\Psi^1)$, Propositions 3 and 5 imply that the entire lifted inequality can be derived from Ψ^1 . Observe also that if conditions (18) and (19) (respectively, conditions (20) and (21) must both be imposed simultaneously for some $i \in M_q$ (respectively, $j \in N_q$), then the problem of finding lifting coefficients will likely be infeasible [[38], Corollary 4, [1], Example 4].

Example 10. Since $\hat{\Psi}^2(z) = \hat{\Psi}^3(z) = \hat{\Psi}^4(z)$ are superadditive over $\mathcal{S} = \mathbb{R}^-$, the above result shows that valid lifting coefficients (α_2, β_2) are obtained if $\alpha_2 \geq -\hat{\Psi}^2(-0)$ and $\beta_2 \geq -\lim_{\lambda \rightarrow 0^+} \frac{\hat{\Psi}^2(-\lambda B_2^*)}{\lambda} = 1$. Similarly, $\alpha_3 \geq 0$ and $\alpha_4 \geq 0$ with $\beta_3 \geq 1$ and $\beta_4 \geq 1$. Therefore the lifted inequality is

$$y_0 + y_1 + y_2 + y_3 + y_4 \leq 27 + x_0 + x_1. \quad (22)$$

In the above example, lifting coefficients α_2, α_3 and α_4 are not strongest and can be chosen equal to -1

Sequential Lifting Coefficients. Sequential lifting (i.e., the case where $|M_k| + |N_k| = 1$ for all $k = 1, \dots, q$) has received much attention in the literature. When lifting a single integer or continuous variable, call it z_q , condition (12) reduces to

$$\alpha_q(z_q - \bar{z}_q) \leq \Psi^q(A_q(z_q - \bar{z}_q)) \quad \forall z_q \in \mathcal{P}^q.$$

This condition can be rewritten as $\underline{\alpha}_q \leq \alpha_q \leq \bar{\alpha}_q$, where

$$\begin{aligned} \bar{\alpha}_q &:= \inf \left\{ \frac{\Psi^q(A_q(z_q - \bar{z}_q))}{z_q - \bar{z}_q} \mid z_q > \bar{z}_q \right. \\ &\quad \left. \text{and } z_q \in \mathcal{P}^q \right\} \\ \text{and } \underline{\alpha}_q &:= \sup \left\{ \frac{\Psi^q(A_q(z_q - \bar{z}_q))}{z_q - \bar{z}_q} \mid z_q < \bar{z}_q \right. \\ &\quad \left. \text{and } z_q \in \mathcal{P}^q \right\}. \end{aligned}$$

When $\bar{\alpha}_q < \underline{\alpha}_q$, lifting is impossible. When Ψ^q is superadditive, the result of the above problem reduces to that shown in the section titled “Lifting Coefficients from Superadditive Lifting Functions”. In fact, if the variable z_q is an integer, then the minimum in the definition of $\bar{\alpha}_q$ is achieved when $z_q = \bar{z}_q + 1$ and the maximum in the definition of $\underline{\alpha}_q$ is achieved when $z_q = \bar{z}_q - 1$ (provided that these problems are feasible). Similar results hold for continuous variables [17].

ON THE STRENGTH OF THE LIFTING PROCEDURE

We now derive conditions under which lifting produces facet-defining inequalities for MIPs. First observe that, if a point $(x^0, x^1, \dots, x^{q-1}; y^0, y^1, \dots, y^{q-1})$ of $\text{conv}(\mathcal{F}^{q-1}(\bar{x}, \bar{y}))$ satisfies inequality (9) at equality (we refer to such a point as *tight*), then its expansion $(x^0, \dots, x^{q-1}, \bar{x}^q, \dots, \bar{x}^d; y^0, \dots, y^{q-1}, \bar{y}^q, \dots, \bar{y}^d)$ will be tight in the inequality obtained after all variables are lifted. Therefore, the dimensions of the faces of $\text{conv}(\mathcal{F}^q(\bar{x}, \bar{y}))$ that lifted inequalities induce do not decrease as variables are reintroduced.

Example 11. The points $(0, 3)$ and $(1, 4)$ are tight in the seed inequality (8) and therefore their extensions $(\mathbf{0}, 0, 1, 2, 3; \mathbf{3}, 3, 4, 7, 10)$ and $(\mathbf{1}, 0, 1, 2, 3; \mathbf{4}, 3, 4, 7, 10)$ are tight in the lifted inequality (22).

Further, additional tight points might be added during the lifting process if lifting coefficients are adequately chosen. Remember that the derivation of lifting coefficients corresponds to rotating the plane associated with the seed inequality around its hinge until it becomes valid for the set in which the restrictions that $x^q = \bar{x}^q$ and $y^q = \bar{y}^q$ are relaxed. To obtain a strong lifted inequality, the plane must be rotated so that sufficiently many new feasible points become tight. This can be achieved by selecting (α^q, β^q) in such a way that sufficiently many affinely independent points $(x^q, y^q) \in \mathcal{P}^q$ satisfy inequality (12) at equality.

Example 12. The lifted inequality (13) obtained in Example 7 is facet-defining for $\text{conv}(\hat{\mathcal{F}}^1(\bar{x}, \bar{y}))$. In particular, lifting add the tight points (0, 2) (or (1, 0, 1, 2, 3; 5, 2, 4, 7, 10) in expanded form) and (1, 4) (or (0, 1, 1, 2, 3; 3, 4, 4, 7, 10) in expanded form), which were obtained in Example 7.

More generally, we obtain the following result.

Proposition 6. *Assume that inequality (7) defines a t_0 -dimensional face of $\text{conv}(\mathcal{F}^0(\bar{x}, \bar{y}))$. Assume also that, for each $k = 1, \dots, l$, lifting is possible and the coefficients (α^k, β^k) are chosen in such a way that there exists t_k affinely independent points in $\mathcal{P}_k \setminus \{(\bar{x}^k, \bar{y}^k)\}$ that satisfy inequality (12) at equality, then the resulting lifted inequality will be a face of $\text{conv}(\mathcal{F})$ of dimension at least $\sum_{i=0}^l t_i$.*

Proposition 6 is proven by using, for each k , the t^k points (x^k, y^k) that satisfy inequality (12) at equality to build tight points in the lifted inequality of the form $(\bar{x}^0, \dots, \bar{x}^{k-1}, x^k, \bar{x}^{k+1}, \dots, \bar{x}^l; \bar{y}^0, \dots, \bar{y}^{k-1}, y^k, \bar{y}^{k+1}, \dots, \bar{y}^l)$, where $(\bar{x}^0, \dots, \bar{x}^{k-1}, \bar{y}^0, \dots, \bar{y}^{k-1})$ is an optimal solution to $\Psi^k \left(\sum_{i \in M_k} A_i^*(x_i - \bar{x}_i) + \sum_{j \in N_k} B_j^*(y_j - \bar{y}_j) \right)$.

It follows from Proposition 6 that, to obtain strong lifted inequalities, it is desirable to select lifting coefficients so that as many affinely independent points of $\mathcal{P}^l \setminus \{(\bar{x}^l, \bar{y}^l)\}$ as possible satisfy inequality (12) at equality. When such a condition is achieved, we say that lifting is *maximum*.

Exact maximum lifting is often used to generate facet-defining inequalities for MIPs. In particular, if the fixing point $(\bar{x}, \bar{y})$ is such that $\mathcal{F}^k(\bar{x}, \bar{y})$ is full-dimensional for all $k = 0, \dots, l$, if seed inequality (7) is facet-defining for $\text{conv}(\mathcal{F}^0(\bar{x}, \bar{y}))$, if lifting is possible in each lifting round and maximum lifting is performed, then the lifted inequality produced is facet-defining for $\text{conv}(\mathcal{F})$.

Example 13. Consider the lifted inequality (22) obtained in Example 10. This inequality can be shown to define a face of dimension at least 7 for $\text{conv}(\hat{\mathcal{F}})$. In particular, in addition to the points described above,

the lifting of variables (x_2, y_2) added the tight point (1, 0, 1, 2, 3; 4 + ϵ , 3, 4 - ϵ , 7, 10); the lifting of (x_3, y_3) added the tight point (1, 0, 1, 2, 3; 4 + ϵ , 3, 4, 7 - ϵ , 10); and the lifting of (x_4, y_4) added the tight point (1, 0, 1, 2, 3; 4 + ϵ , 3, 4, 7, 10 - ϵ), where ϵ is a sufficiently small positive quantity. These points are easily constructed combining the comment following Proposition 6 and the discussion of the section titled “Sequential Lifting Coefficients”.

Characterizing the strength of an inequality obtained using approximate lifting is more difficult. However, if there is a solution (x^k, y^k) in $\mathcal{P}^k$ that satisfies inequality (12) at equality and that is such that $\Psi^1(z) = \phi(z)$, where $z = \sum_{i \in M_k} A_i^*(x_i - \bar{x}_i) + \sum_{j \in N_k} B_j^*(y_j - \bar{y}_j)$, then its extension is tight in the lifted inequality.

Proposition 7. *Assume that inequality (7) is a t_0 -dimensional face of $\text{conv}(\mathcal{F}^0(\bar{x}, \bar{y}))$. Assume also that, for each $k = 1, \dots, l$, lifting is possible and the coefficients (α^k, β^k) are chosen in such a way that there exists t_k affinely independent points (x^k, y^k) in $\mathcal{P}_k \setminus \{(\bar{x}^k, \bar{y}^k)\}$ that satisfy inequality (12) at equality and that satisfy $\Psi^1(z) = \phi(z)$, where $z = \sum_{i \in M_k} A_i^*(x_i - \bar{x}_i) + \sum_{j \in N_k} B_j^*(y_j - \bar{y}_j)$, then the lifted inequality will be a face of $\text{conv}(\mathcal{F})$ of dimension at least $\sum_{i=0}^l t_i$.*

It is clear from Proposition 7 that approximate lifting can produce facet-defining inequalities if the points for which conditions (12) are satisfied at equality correspond to regions where $\phi(z)$ equals $\Psi^1(z)$. When this is not the case, it seems intuitive that inequalities produced should be weaker than those obtained through exact maximum lifting. This intuition is not always verified as the resulting inequalities may still be facet-defining. An interesting such example is presented in Gu *et al.* [14, pp. 124–125] for the case of the 0–1 knapsack polytope.

LIMIT THEOREMS FOR BRANCHING PROCESSES

PETER JAGERS

SERIK SAGITOV

Department of Mathematical Sciences,
Chalmers University of Technology
and University of Gothenburg,
Gothenburg, Sweden

The classical limit theorems of branching processes show what happens in the long run in a branching population. In principle, they are the same for all types of branching processes, from the simple single-type Galton–Watson process to general processes. (For the corresponding results to hold in multitype frameworks, types should *communicate*, though, in the sense that individuals must be able to get progeny of any type in their line of descent. This requirement may take various technical forms, and in infinite or abstract type spaces further conditions are needed [1].) The limit theorems describe exponential growth of supercritical processes and polynomial growth of critical processes, conditioned not to die out, and the convergence of subcritical populations, conditioned upon nonextinction. In the supercritical case, there are also theorems about the stabilization of population composition. For simple processes, there is only the kin structure to stabilize, but for age-dependent and general processes, the age-distribution becomes an important property, and for multitype processes evolution and possible limits of type distribution is an obvious topic.

GALTON–WATSON PROCESSES

Let $\{Z_n; n = 0, 1, 2, \dots\}$, $Z_0 = 1$ be a Galton–Watson process and X a random variable with the offspring distribution of that process. Write $m = E[X]$ for the reproduction mean, $\sigma^2 = \text{Var}[X]$, and $f(s) = E[s^X]$ for the

reproduction generating function. The logarithmic moment condition $E[X \log X] < \infty$ (which is weaker than $\sigma^2 < \infty$) is referred to as the $x \log x$ -condition.

1. Consider a subcritical process, that is, $m < 1$, satisfying $x \log x$. Then, there is a constant $0 < c \leq 1$, such that $P(Z_n > 0) \sim cm^n$. Further, $\lim_{n \rightarrow \infty} P(Z_n = k \mid Z_n > 0) = a_k$ exists, $\sum_{k=1}^{\infty} a_k = 1$, and the generating function $g(s) = \sum_{k=1}^{\infty} a_k s^k$ satisfies $g \circ f = mg + 1 - m$.
2. If $\{Z_n\}$ is critical (i.e., $m = 1$) and $\sigma^2 < \infty$, then the survival probability $P(Z_n > 0) \sim 2/(\sigma^2 n)$ and the process grows linearly, if conditioned upon survival: $E[Z_n \mid Z_n > 0] \sim \sigma^2 n/2$ and $P(Z_n/n \leq u \mid Z_n > 0) \rightarrow 1 - \exp(-2u/\sigma^2)$, as $n \rightarrow \infty$.
In the case of infinite variance $\sigma^2 = \infty$, a more general limit theorem involves a parameter $\gamma \in (0, 1]$ indicating the heaviness of the distribution tail $P(X > n) \sim cn^{1+\gamma}$. Since $P(Z_n > 0) \sim c'n^{-1/\gamma}$, the population growth conditional on nonextinction becomes polynomial of order $n^{1/\gamma}$.
3. If the process is supercritical, then there is a random variable $W \geq 0$, such that almost surely $Z_n \sim Wm^n$, as $n \rightarrow \infty$. If the $x \log x$ -condition holds, then convergence takes place in the mean as well, $W > 0$ almost surely on the set of nonextinction, and the Laplace transform ϕ of W , $\phi(s) = E[e^{-sW}]$, is the unique solution of the functional equation $\phi(mu) = f \circ \phi(u)$, $\phi'(0) = -1$. If the condition does not hold, $W = 0$ [2,3,14].

SINGLE-TYPE GENERAL PROCESSES

Now let $\{Z_t^X, t \geq 0\}$ denote a general branching process, starting from one newborn ancestor at time $t = 0$, and counted by

the *characteristic* χ . This means that for each individual there is a reproduction point process ξ , and an age-dependent characteristic $\chi \geq 0, \chi(a)$ interpreted as the weight of the individual at age a , so that Z_t^χ is the sum of all individuals' χ -values evaluated at their age at time t . The random characteristic χ is usually bounded and taken to vanish for negative a , so that unborn individuals do not contribute. The ξ of different individuals are supposed to be i.i.d. and so are the characteristics (for further details see Ref. 5). The simplest characteristic would just be 1 while the individual is alive, and 0 otherwise, implying $E[\chi(a)] = 1 - L(a)$, where L stands for the life length distribution. That way the process value reduces to the number of individuals alive. The process counted by that characteristic is usually denoted just $\{Z_t, t \geq 0\}$. Another characteristic would equal 1 if the individual is alive and younger than some given age, yielding the age distribution. In specific applications, the characteristic could refer to kin structure (pedigree) or body mass, number of cousins, and so on.

Write $\mu(a) = E[\xi(a)]$, assume $\mu(0) < 1$, so as to avoid the possibility of instantaneous explosion, and define the *Malthusian parameter* α by

$$\begin{aligned} \hat{\mu}(\alpha) &= \int_0^\infty e^{-\alpha t} \mu(dt) = E[\hat{\xi}(\alpha)] \\ &= E\left[\int_0^\infty e^{-\alpha t} \xi(dt)\right] = 1, \end{aligned}$$

hat denoting the Laplace(–Stieltjes) transform. If we write $m = \mu(\infty)$ for the expected offspring number of an individual during all her life, then m is larger than, smaller than, or equal to 1 together with α having the same relation to 0, that is the process being supercritical, subcritical, or just critical. A crucial entity is

$$\beta = \int_0^\infty u e^{-\alpha u} \mu(u) du,$$

the mean age at child-bearing. In the case $\beta < \infty$ the $x \log x$ -condition takes the form

$$E[\hat{\xi}(\alpha) \log \xi(\infty)] < \infty.$$

The main limit theorems below are formulated for what is called the *nonlattice* case for simplicity. It means that there is no lattice where all events can take place, like the lattice of positive numbers, or the multiples of some distance. The results all have lattice equivalents, covering thus discrete-time branching processes. Technical assumptions (like on measurability and smoothness) are omitted. The discrete-time case is treated in Ref. 4. As mentioned, this article is also limited to single-type populations. General multitype theory can be found in Ref. 1 and 6.

In the Galton–Watson case, $E[Z_n] = m^n$. For Markov branching processes in continuous-time, that is the (very) special case where life spans are exponentially distributed and mothers split into a random number of children at death, the offspring number independent of life span, the expected population size, analogously, grows exactly like $e^{\alpha t}$. For general processes, only an asymptotic such relation holds. Indeed, consider a characteristic which is independent of the past, that is, its value is determined by the lives of an individual and its progeny, and of course the individual's present age. By the renewal theorem [5], for example,

$$\lim_{t \rightarrow \infty} e^{-\alpha t} E[Z_t^\chi] = \int_0^\infty e^{-\alpha u} E[\chi(u)] du / \beta = c(\chi),$$

under minor conditions on the characteristic.

The three classical limit theorems take the form:

1. Consider a subcritical process, that is, $m < 1$, satisfying $x \log x, \beta < \infty$, and having a life length distribution L with $\int_0^\infty t e^{-\alpha t} L(dt) < \infty$. Then, there is an $0 < r \leq 1$, such that $P(Z_t > 0) \sim r e^{\alpha t}$. (Recall that $\alpha < 0$!) Further, $P(Z_t^\chi \leq y | Z_t > 0)$ weakly converges to a proper distribution with mean $c(\chi)/r$, [7].
2. In the critical case $\alpha = 0$, if $\sigma^2 < \infty$ and $1 - L(t) = o(t^{-2})$ as $t \rightarrow \infty$, then $P(Z_t > 0) \sim 2\beta/\sigma^2 t$. The process Z_t^χ divided by $\sigma^2 t/2$ and conditioned on

$Z_t > 0$, has an asymptotic exponential distribution with mean $c(\chi) = \int_0^\infty E[\chi(u)] du / \beta$, [7,8].

The case of heavy tailed life lengths, when $t^2(1 - L(t)) \rightarrow d$ with $0 < d \leq \infty$, brings essentially new limit results as the survival event can be due to just few long-living individuals, [9,10].

3. If, finally, the process is supercritical, then there is a random variable $W \geq 0$, such that almost surely $Z_t^\chi \sim c(\chi)W e^{\alpha t}$, almost surely as $t \rightarrow \infty$, provided the characteristic is independent of the past. (Characteristics that describe history are important for the studies of pedigrees, but here the limit takes a more complex form.) If the $x \log x$ -condition holds, then convergence takes place in the mean as well, and $W > 0$ almost surely on the set of nonextinction.

A consequence of (2) and (3) is that population composition stabilizes under growth. For suitable characteristics χ ,

$$\lim_{t \rightarrow \infty} Z_t^\chi / Z_t = \frac{\int_0^\infty e^{-au} E[\chi(u)] du}{\int_0^\infty e^{-au} (1 - L(u)) du},$$

since the expected value of the characteristic that tells if an individual is alive at age u is precisely $1 - L(u)$. As a linear functional in the characteristics, these ratios define a stable probability measure on a doubly infinite pedigree space (past and future), which describes the history and present composition of populations [6,11,12,13]. Some further general references are the books [15,16,17].

LIMIT THEOREMS FOR MARKOV RENEWAL PROCESSES

SERHAN ZIYA
Department of Statistics and
Operations Research,
University of North Carolina,
Chapel Hill, North Carolina

MARKOV RENEWAL-TYPE EQUATION

Suppose that $\{(X_n, T_n), n \geq 0\}$ is a Markov renewal sequence with kernel $G(\cdot)$ and X_n takes values from the discrete set E . We define $\{X(t), t \geq 0\}$ to be the semi-Markov process generated by this Markov renewal sequence. Specifically, for any $t \geq 0$, we let $X(t) = X_{N(t)}$ where

$$N(t) = \inf\{n \geq 0 : T_n \leq t\}. \quad (1)$$

We define $N(t) = \{[N_k(t)]_{k \in E}, t \geq 0\}$ to be the Markov renewal process, and $\{M(t), t \geq 0\}$ to be the Markov renewal function generated by the Markov renewal sequence $\{(X_n, T_n), n \geq 0\}$. In other words, for any $s \geq 0$, and $k \in E$, $N_k(s)$ is the number of times the semi-Markov process $\{X(t), t \geq 0\}$ entered the state k over $(0, s]$ and $M_{ik}(s)$ is its expectation conditional on the initial state being $i \in E$; that is,

$$M_{ik}(s) = \mathbf{E}[N_k(s) | X_0 = i] \text{ for } i, k \in E \text{ and } s \geq 0.$$

First, we introduce the matrix convolution notation, which will make the presentation significantly simpler. Suppose that $A(t) = [A_{jk}(t)]$ and $B(t) = [B_{jk}(t)]$ are two matrices of functions for which the product $A(t)B(t)$ is defined. Now let

$$\begin{aligned} C_{jk}(t) &= \sum_i \int_0^t A_{ji}(t-u) dB_{ik}(u) \\ &= \sum_i \int_0^t dA_{ji}(u) B_{ik}(t-u). \end{aligned}$$

Then, the matrix $C(t) = [C_{ij}(t)]$ is called the *convolution* of A and B (and written as $C(t) = A * B(t)$).

Now, any equation in the form of

$$R(t) = D(t) + G * R(t), \quad (2)$$

where $D(\cdot)$ is known and $R(\cdot)$ is a functional matrix, which one tries to solve for, is called a Markov renewal-type equation. Such equations are typically obtained by using the Markov renewal argument; that is, by conditioning on X_1 and T_1 . Under certain technical conditions, a closed-form expression for $R(t)$ is known, but this expression is usually not helpful as it requires complete knowledge of the Markov renewal function associated with the Markov renewal sequence. The limiting analysis, which is the subject of this article, is relatively easier.

KEY MARKOV RENEWAL THEOREM

First, we introduce new notation which will be useful in stating the Key Markov Renewal Theorem. Let

$$S_j = \inf\{t \geq T_1 : X(t) = j\}, j \in E;$$

$$\tau_i = \mathbf{E}[T_1 | X(0) = i], i \in E;$$

and

$$\tau_{ij} = \mathbf{E}[S_j | X(0) = i], i, j \in E.$$

Thus, S_j is the time of the first visit to state j at or after T_1 and τ_{ij} is its expectation given that the initial state is i . We also define

$$\theta_{ij} = \mathbf{E}[T_1 | X_0 = i, X_1 = j], i, j \in E;$$

$$a_i^2 = \mathbf{E}[T_1^2 | X_0 = i], i \in E;$$

and

$$a_{ij}^2 = \mathbf{E}[S_j^2 | X_0 = i], i, j \in E.$$

Finally, we define

$$\alpha_{ij} = \lim_{t \rightarrow \infty} \left(M_{ij}(t) - \frac{t}{\tau_{jj}} \right),$$

which can be shown to be equal to Ref. 1.

$$\alpha_{ij} = \begin{cases} \frac{a_{ii}^2 - 2\tau_{ii}^2}{2\tau_{ii}^2} & i = j, \\ \frac{a_{ij}^2 - 2\tau_{ij}\tau_{ji}}{2\tau_{jj}^2} & i \neq j. \end{cases}$$

The Key Markov Renewal Theorem gives an expression for $R(t)$ as $t \rightarrow \infty$. The theorem requires a number of technical conditions to hold. We first state these conditions:

Condition 1. Suppose that $H_j(\cdot)$ is the sojourn time distribution for state j for the Markov renewal sequence $\{(X_n, T_n), n \geq 0\}$ and suppose that there exists positive ε and α such that $H_i(\alpha) < 1 - \varepsilon$ for $i \in E$. Note that, as Kulkarni [1] shows, this condition essentially ensures that the process $\{N(t), t \geq 0\}$ as defined in Equation (1) is regular; that is, $N(t) < \infty$ for all $0 \leq t < \infty$ with probability 1.

Condition 2. The semi-Markov process $\{X(t), t \geq 0\}$ is irreducible, aperiodic, positive recurrent with a limiting distribution $\{p_j, j \in E\}$.

Condition 3. The functional matrix $D(t) = [D_{ij}(t)]$ satisfies the following:

- (i) $|D_{ij}(t)| \leq d_j(t) < \infty$ for $i \in E$ and $t \geq 0$,
- (ii) For all $i, j \in E$, $D_{ij}(t)$ can be written as a difference of two nonnegative bounded monotone functions.
- (iii) The limit $d_{ij} = \lim_{t \rightarrow \infty} D_{ij}(t)$ exists for all $i, j \in E$.
- (iv) For all $i, j \in E$, $\int_0^\infty (D_{ij}(t) - d_{ij}) dt < \infty$.
- (v) For all $j \in E$, $\int_0^\infty \sum_{k \in E} \frac{p_k}{\tau_k} D_{kj}(t) dt < \infty$.

If all these three conditions hold, the Key Markov Renewal Theorem says that

$$\lim_{t \rightarrow \infty} R_{ij}(t) = d_{ij} + \sum_{k \in E} \alpha_{ik} d_{kj} + \int_0^\infty \sum_{k \in E} \frac{p_k}{\tau_k} D_{kj}(t) dt. \quad (3)$$

Note that if $d_{ij} = 0$ for all $i, j \in E$, the first two terms in Equation (3) drop and the equation simplifies to

$$\lim_{t \rightarrow \infty} R_{ij}(t) = \int_0^\infty \sum_{k \in E} \frac{p_k}{\tau_k} D_{kj}(t) dt. \quad (4)$$

EXAMPLE: LIMITING BEHAVIOR OF MARKOV REGENERATIVE PROCESSES

In this section, we show how the key Markov renewal theorem can be used to derive the limiting probability distribution for Markov regenerative processes. Suppose that $\{Z(t), t \geq 0\}$ is a Markov regenerative process with an embedded Markov renewal sequence $\{(X_n, T_n), n \geq 0\}$ with kernel $G(\cdot)$ and taking values in a discrete set E .

Define

$$R_{ij}(t) = P\{Z(t) = j | Z(0) = i\} \text{ for } i, j \in E.$$

First, we use a Markov renewal argument to find an expression for $R_{ij}(t)$. Specifically, conditioning on X_1 and T_1 , we get

$$\begin{aligned} P\{Z(t) = j | X_0 = i, X_1 = k, T_1 = s\} \\ = \begin{cases} R_{kj}(t-s), & s \leq t \\ P\{Z(t) = j | X_0 = i, X_1 = k, T_1 = s\}, & s > t \end{cases} \end{aligned}$$

This leads to

$$\begin{aligned} R_{ij}(t) &= \int_0^t \sum_{k \in E} R_{kj}(t-s) dG_{ik}(s) \\ &\quad + \int_t^\infty \sum_{k \in E} P\{Z(t) = j | X_0 = i, X_1 = k, \\ &\quad T_1 = s\} dG_{ik}(s). \end{aligned}$$

Then, we have

$$\begin{aligned} R_{ij}(t) &= P\{Z(t) = j, T_1 > t | X_0 = i\} \\ &\quad + [G * R(t)]_{ij}, \end{aligned} \quad (5)$$

which, in matrix form, can also be written as

$$R(t) = D(t) + G * R(t), \quad (6)$$

where $D(t) = [D_{ij}(t)]$ is defined by

$$D_{ij}(t) = P\{Z(t) = j, T_1 > t | Z(0) = i\} \text{ for } i, j \in E.$$

Note that Equation (6) is a Markov renewal-type equation.

Now, suppose that the sample paths of the Markov regenerative process $\{Z(t), t \geq 0\}$ are right continuous with left limits, and the semi-Markov process generated by the Markov renewal sequence $\{(X_n, T_n), n \geq 0\}$ is irreducible, aperiodic, and positive recurrent with limiting distribution $[p_j, j \in E]$. One can then verify that all the conditions of the key Markov renewal theorem, as stated in the previous section titled “Key Markov Renewal Theorem,” hold and one can see that $\lim_{t \rightarrow \infty} D_{ij}(t) = 0$ for any $i, j \in E$. Thus, from Equation (4), we get

$$\lim_{t \rightarrow \infty} R_{ij}(t) = \int_0^\infty \sum_{k \in E} \frac{p_k}{\tau_k} D_{kj}(s) ds \text{ for } i, j \in E. \quad (7)$$

Let β_{kj} denote the expected time the Markov regenerative process $\{Z(t), t \geq 0\}$ spends in state j during $(0, T_1)$ given that $X_0 = k$. One can then show that (see Ref. 1 for a complete derivation)

$$\beta_{kj} = \int_0^\infty D_{kj}(t) dt.$$

Plugging this in Equation (7), we find

$$\lim_{t \rightarrow \infty} P\{Z(t) = j | X_0 = i\} = \sum_{k \in E} \frac{p_k}{\tau_k} \beta_{kj} \text{ for } i, j \in E.$$

LIMIT THEOREMS FOR RENEWAL PROCESSES

NAN LIU

Department of Health Policy and
Management, Mailman School of
Public Health, Columbia
University, New York,
New York

This article describes the *key renewal theorem* (KRT) and *Blackwell's renewal theorem* (BRT). These two limit theorems appear in different forms, but can be shown to be equivalent. For ease of presentation, we follow the terminology used in Karlin and Taylor [1] and refer to them collectively as the *renewal theorem* (RT). The RT is a very useful tool for characterizing the asymptotic behavior of a probabilistic quantity of interest in a *renewal process* (RP). To start, we briefly review renewal processes and the *elementary renewal theorem* (ERT).

An RP is a counting process with independent and identically distributed (iid) inter-event times. Mathematically, it can be defined as follows. Let $S_0 = 0$, and S_n be the occurrence time of the n th event, $n \geq 1$. Assume that

$$0 \leq S_1 \leq S_2 \leq S_3 \leq \dots$$

Define

$$X_n = S_n - S_{n-1}, \quad n \geq 1.$$

Thus $\{X_n, n \geq 1\}$ is a sequence of inter-event times. Next define

$$N(t) = \sup\{n \geq 0 : S_n \leq t\}.$$

Then $N(t)$ is called an RP generated by $\{X_n, n \geq 1\}$ if $\{X_n, n \geq 1\}$ is a sequence of nonnegative iid random variables. We refer the readers to the article titled **Definition and Examples of Renewal Processes** in this encyclopedia for a detailed introduction and more examples of RPs.

Suppose that the inter-event times $\{X_n, n \geq 1\}$ have a common cumulative distribution function (cdf) $G(\cdot)$, that is, $P(X_n \leq t) = G(t)$, $n \geq 1$. Let τ and σ^2 represent the mean and variance of X_1 , respectively. To avoid triviality, we assume that $G(0^-) = 0$ and $G(0^+) = G(0) < 1$, which imply that $\tau > 0$. Let

$$M(t) = E(N(t)), \quad t \geq 0.$$

The function $M(t)$ is called the *renewal function* (RF), which is simply the expected number of events (renewals) up to time t . The ERT states that

$$\lim_{t \rightarrow \infty} \frac{M(t)}{t} = \frac{1}{\tau}, \quad (1)$$

which implies the following asymptotic relation $M(t) \sim t/\mu$ as $t \rightarrow \infty$. As a sample path version of the ERT, we have

$$\lim_{t \rightarrow \infty} \frac{N(t)}{t} = \frac{1}{\tau}, \quad \text{with probability 1,} \quad (2)$$

which is a result from the strong law of large numbers. However, the ERT does not follow from Equation (2) directly since almost sure convergence does not imply convergence of expected values. A more intricate proof is needed to show the ERT. We refer the readers to the article titled **Renewal Function and Renewal-Type Equations** in this encyclopedia for an indepth discussion on the RF and ERT.

Blackwell's renewal theorem, which was proposed by David Blackwell (Professor Emeritus of Statistics at the University of California, Berkeley), can be regarded as a refinement of this asymptotic relation. It asserts that for any $h > 0$

$$M(t+h) - M(t) \rightarrow \frac{h}{\tau}, \quad \text{as } t \rightarrow \infty,$$

under certain mild conditions on $G(\cdot)$. In words, the expected number of renewals during an interval of length h is approxi-

mately h/τ , provided that the process has already run for a long time. This result can be easily verified in a Poisson process, a special case of RPs.

In the next section, we first describe the KRT, which is equivalent to the BRT but of a different form. The KRT provides a convenient setting for the application of RT. Then we formally present the BRT, and briefly discuss its connection with the KRT.

THE RENEWAL THEOREM

The KRT reveals the asymptotic behavior of the solution to a *renewal-type equation*, which has the following form:

$$H(t) = D(t) + \int_0^t H(t-x) dG(x), \quad (3)$$

where $D(\cdot)$ is a known function, $G(\cdot)$ is the cdf of inter-event times, and $H(t)$ is to be determined. Renewal-type equations often arise when using the *renewal argument*, which is a method to derive probabilistic quantities in RPs by conditioning on the occurrence time of the first event, that is, S_1 . We refer the readers to the article titled **Renewal Function and Renewal-Type Equations** in this encyclopedia for an introduction of the renewal-type equation and renewal argument. In this section, we focus on the asymptotic behavior of $H(t)$.

Before presenting the KRT, we need the following definition.

Definition 1 [Periodic Random Variables]. A nondefective random variable X (or its distribution) is called *periodic* (or *arithmetic*, or *lattice*) if there exists a $d > 0$ such that

$$\sum_{k=0}^{\infty} P(X = kd) = 1.$$

The largest value of d for which the above equality holds is called the *period* (or *span*) of the random variable X (or its distribution).

If a random variable X is not periodic, it is called *aperiodic* (or *non-arithmetic*, or *non-lattice*). We refer the readers to Kulkarni [2]

for more examples on periodic and aperiodic random variables. Note that all continuous random variables are aperiodic.

Theorem 1 [Key Renewal Theorem]. Let $H(t)$ be a solution to the renewal-type equation (3). Suppose that $D(t)$ is a monotonic function which is absolutely integrable in the sense that

$$\int_0^{\infty} |D(t)| dt < \infty.$$

(i) If $G(\cdot)$ is aperiodic with mean $\tau > 0$, then

$$\lim_{t \rightarrow \infty} H(t) = \begin{cases} \frac{1}{\tau} \int_0^{\infty} D(t) dt & \text{if } \tau < \infty, \\ 0 & \text{if } \tau = \infty. \end{cases}$$

(ii) If $G(\cdot)$ is periodic with period d and mean $\tau > 0$, then for $0 \leq x < d$,

$$\begin{aligned} & \lim_{k \rightarrow \infty} H(kd + x) \\ &= \begin{cases} \frac{d}{\tau} \sum_{k=0}^{\infty} D(kd + x) & \text{if } \tau < \infty, \\ 0 & \text{if } \tau = \infty. \end{cases} \end{aligned}$$

We refer to Feller [3] for a proof of the KRT. In his proof, Feller assumes that the function $D(t)$ is *directly Riemann integrable*. Feller's condition is technical, and not presented here. The condition we gave above is a simple and sufficient condition for Feller's, and suffices for most of the applications of the KRT. As noted in Tijms [4], a more general condition guaranteeing $D(t)$ to be directly Riemann integrable is that $D(t)$ can be written as a finite sum of monotone, integrable functions.

As mentioned earlier, another form of the KRT is the BRT, which is expressed more explicitly in terms of the renewal function $M(t)$. We present the BRT below, and follow the convention that $h/\tau = 0$ if $\tau = \infty$.

Theorem 2 [Blackwell's Renewal Theorem]. Let $h > 0$ be a fixed number.

(i) If $G(\cdot)$ is aperiodic with mean $\tau > 0$, then

$$\lim_{t \rightarrow \infty} [M(t+h) - M(t)] = \frac{h}{\tau}.$$

(ii) If $G(\cdot)$ is periodic with period d and mean $\tau > 0$, then

$$\lim_{t \rightarrow \infty} [M(t+h) - M(t)] = \frac{h}{\tau},$$

provided that h is a multiple of the period d .

The BRT and the KRT can be shown to be equivalent. The proof of BRT using the KRT can be found in Karlin and Taylor [1] and Kulkarni [2]. As discussed in Karlin and Taylor [1] and Ross [5], the KRT can also be deduced from the BRT by approximating a directly Riemann integrable function with step functions.

The next section presents two classical applications of the KRT. We discuss the limiting distributions of recurrence times (including the current age, excess life, and total life) in an RP, and the asymptotic expansion of a renewal function. We briefly mention how the KRT can be used to find these results. Detailed derivations can be found in Karlin and Taylor [1], Kulkarni [2], and Ross [5].

APPLICATIONS OF THE KEY RENEWAL THEOREM

Limiting Distributions of Recurrence Times

The following three probabilistic quantities related to event times are of particular interest in the study of RPs:

$$\begin{aligned} A(t) &= t - S_{N(t)}, \\ B(t) &= S_{N(t)+1} - t, \\ L(t) &= S_{N(t)+1} - S_{N(t)} \\ &= X_{N(t)+1} = A(t) + B(t), \end{aligned} \quad (4)$$

where $t \geq 0$.

Physically, $A(t)$ represents the time elapsed from the latest event before t to time t , and $B(t)$ represents the time duration between t and the next event immediately after t . Their sum $L(t)$ is the total inter-event time that contains t . The quantities $A(t)$, $B(t)$, and $L(t)$ are called the current age, remaining life (excess

life), and total life at time t , respectively. Sometimes $A(t)$ is also called the backward recurrence time and $B(t)$ is called the forward recurrence time. The stochastic processes $\{A(t), t \geq 0\}$, $\{B(t), t \geq 0\}$, and $\{L(t), t \geq 0\}$ are called the *age process*, *remaining life process*, and *total life process*, respectively.

In this section, we discuss the asymptotic behavior of these three processes. Suppose that $G(\cdot)$ is aperiodic and $\tau < \infty$. Then the following results can be shown by using the KRT:

$$\begin{aligned} \lim_{t \rightarrow \infty} \mathbf{P}(A(t) > x) &= \lim_{t \rightarrow \infty} \mathbf{P}(B(t) > x) \\ &= \frac{1}{\tau} \int_x^\infty (1 - G(u)) du, \end{aligned} \quad (5)$$

$$\lim_{t \rightarrow \infty} \mathbf{P}(A(t) > x, B(t) > y) = \frac{1}{\tau} \int_{x+y}^\infty (1 - G(u)) du,$$

and

$$\lim_{t \rightarrow \infty} \mathbf{P}(L(t) > x) = \frac{1}{\tau} \int_x^\infty u dG(u). \quad (6)$$

To facilitate understanding, we present how to derive Equation (5) by applying the KRT, and other results can be shown in a similar way. We start with the derivation of the limiting distribution of $B(t)$. Let $H(t) = \mathbf{P}(B(t) > x)$. Then conditioning on the occurrence time of the first renewal event $X_1 = u$, we have

$$\begin{aligned} \mathbf{P}(B(t) > x | X_1 = u) \\ &= \begin{cases} H(t-u) & \text{if } 0 \leq u \leq t \\ 0 & \text{if } t < u \leq x+t \\ 1 & \text{if } u > x+t. \end{cases} \end{aligned}$$

Unconditioning, we get

$$\begin{aligned} H(t) &= \int_0^\infty \mathbf{P}(B(t) > x | X_1 = u) dG(u) \\ &= \int_0^t H(t-u) dG(u) + \int_{x+t}^\infty dG(u) \\ &= \int_0^t H(t-u) dG(u) + 1 - G(x+t). \end{aligned}$$

Now, for a fixed $x > 0$, $1 - G(x + t)$ is nonnegative and nonincreasing for $t \geq 0$, and

$$\int_0^\infty (1 - G(x + t)) dt \leq \int_0^\infty (1 - G(t)) dt = \tau < \infty.$$

Hence the conditions for the KRT are satisfied, from which it directly follows that

$$\begin{aligned} \lim_{t \rightarrow \infty} \mathbf{P}(B(t) > x | X_1 = u) &= \frac{1}{\tau} \int_0^\infty (1 - G(x + t)) dt \\ &= \frac{1}{\tau} \int_x^\infty (1 - G(t)) dt. \end{aligned}$$

To derive the limiting distribution for $A(t)$, first notice that for $t > x$, $\{A(t) > x\} \Leftrightarrow \{\text{No renewals in } [t - x, t]\} \Leftrightarrow \{B(t - x) > x\}$. Thus,

$$\begin{aligned} \lim_{t \rightarrow \infty} \mathbf{P}(A(t) > x) &= \lim_{t \rightarrow \infty} \mathbf{P}(B(t - x) > x) \\ &= \lim_{t \rightarrow \infty} \mathbf{P}(B(t) > x). \end{aligned}$$

This completes the derivation of Equation (5).

Applying the KRT, one can further show that

$$\lim_{t \rightarrow \infty} \mathbf{E}(A(t)) = \lim_{t \rightarrow \infty} \mathbf{E}(B(t)) = \frac{\sigma^2 + \tau^2}{2\tau} \quad (7)$$

and

$$\lim_{t \rightarrow \infty} \mathbf{E}(L(t)) = \frac{\sigma^2 + \tau^2}{\tau}. \quad (8)$$

However, we should remind the readers that Equations (7) and (8) cannot be directly deduced from Equations (5) and (6), respectively, since convergence in distribution does not imply convergence of expected values. Hence, one should resort to the KRT for a

proof. See, for example, Kulkarni [2], for a detailed derivation.

Below we introduce an interesting phenomenon called *inspection paradox* in relation to Equations (4) and (8). Recall from Equation (4) that $L(t) = X_{N(t)+1}$, but Equation (8) says that

$$\lim_{t \rightarrow \infty} \mathbf{E}(X_{N(t)+1}) = \frac{\sigma^2 + \tau^2}{\tau} \geq \tau = \mathbf{E}(X_n),$$

that is, for a large t , the inter-event time that covers t is on average longer than a generic inter-event interval. This counterintuitive phenomenon is known as the inspection paradox. In fact, one can further show that, for a fixed $t \geq 0$,

$$\mathbf{P}(X_{N(t)+1} > x) \geq \mathbf{P}(X_1 > x). \quad (9)$$

In words, the length of the renewal interval that contains time t is *stochastically larger* than the first renewal interval. This immediately implies that

$$\mathbf{E}(X_{N(t)+1}) \geq \mathbf{E}(X_1).$$

To understand this paradox, let us first fix an arbitrary point t . We measure the length of the interval containing t . However, it seems plausible that the longer the duration of an interval, the larger the likelihood that it would be experienced and measured. Such samplings are known as *length-biased sampling*, and occur in many sampling situations. Stein and Dattero [6] provide introductory examples to illustrate such sampling bias and the inspection paradox. For a mathematical proof of Equation (9), the readers are referred to Angus [7] and Ross [8].

Now, let us consider a concrete example. Let $\{N(t), t \geq 0\}$ be a Poisson process with mean inter-event time $1/\lambda$. It can be shown that (see, for example, Chapter 5.3 of Karlin and Taylor [1])

$$\mathbf{E}(L(t)) = \frac{1}{\lambda} + \frac{1}{\lambda}(1 - e^{-\lambda t}) \geq \frac{1}{\lambda} = \mathbf{E}(X_1).$$

We see that, as $t \rightarrow \infty$, the mean total life doubles the mean inter-event time!

Asymptotic Expansion of the Renewal Function

Recall that the ERT implies that

$$M(t) = \frac{t}{\tau} + o(t),$$

where $o(t)$ represents a function $f(t)$ such that $f(t)/t \rightarrow 0$ as $t \rightarrow \infty$. We are now interested in refining this asymptotic approximation of $M(t)$. To do this, we study the function $o(t)$, and give the second term of the asymptotic expansion of $M(t)$. Suppose that $\sigma^2 < \infty$ and $G(\cdot)$ is aperiodic. To start, we define

$$H(t) = M(t) - \frac{t}{\tau},$$

and then apply the renewal argument, which leads to a renewal-type equation with $H(t)$ as its solution. From this renewal-type equation, one is able to identify the function $D(t)$, and verify that $D(t)$ can be written as a sum of two monotone functions both of which are absolutely integrable. Thus, the KRT is directly applicable, and it follows that

$$\lim_{t \rightarrow \infty} \left[M(t) - \frac{t}{\tau} \right] = \frac{1}{\tau} \int_0^\infty D(t) dt = \frac{\sigma^2 - \tau^2}{2\tau^2},$$

or equivalently

$$M(t) = \frac{t}{\tau} + \frac{\sigma^2 - \tau^2}{2\tau^2} + o(1), \quad (10)$$

where $o(1)$ is a function of t which approaches 0 as $t \rightarrow \infty$. This expansion gives a more accurate estimate of $M(t)$ for large t , and implies that t/τ overestimates $M(t)$ for large t if the coefficient of variation $\sigma^2/\tau^2 < 1$. Consider a Poisson process, where $\sigma^2 = \tau^2$, and in fact $M(t) = t/\tau$, verifying Equation (10) in this special case of RPs.

FURTHER READINGS

Further details on these two limit theorems for RPs, namely, the KRT and the BRT, can be found in classical textbooks including Karlin and Taylor [1], Kulkarni [2], and Ross [5]. Two seminal papers that prove the BRT and the KRT are Blackwell [9] and Smith [10], respectively. To track the theoretical development of these limit theorems and in general

the renewal theory, we refer the readers to Smith [11].

These limit theorems are very useful tools in the study of stochastic processes. They are used in the proof of those key results in alternating renewal processes and regenerative processes [2,5,12]. These two processes are discussed in the articles titled **Alternating Renewal Processes** and **Regenerative Processes** in this encyclopedia, respectively. The two limit theorems have also been extensively used in the study of queueing theory, inventory control, and warranty management. Literature on these applications is enormous. We provide a few examples in relevance to those applications of the KRT discussed above.

The remaining life in RPs is widely used in stochastic modeling. In queueing theory, it is the remaining service time; in the context of inventory control, it is the undershoot of the reorder point. By considering only those times when the server is busy, the remaining service time seen by an arriving customer in an M/G/1 queue is equivalent to the remaining life in a RP generated by a nonstopping service process [13,14]. Using this result, one can construct a proof for the famous Pollaczek–Khinchine formula, and study the distribution of waiting times in an M/G/1 queue [15]. Karlin [16] discusses the application of renewal theory to the study of inventory control. In particular, he applies the excess life in the study of a periodic review inventory system managed by an (s, S) policy. Green [17] extends the study of limiting distribution of recurrence times. She shows that the asymptotic joint distribution of the remaining life and total life of an subinterval is that of an RP generated by these subintervals only, if attention is restricted to these subintervals.

The RF plays an important role in the cost analysis of warranty management. Many asymptotic results are available for approximating RFs involved in such cost computations. Feller [3] and Cox and Miller [18] provide asymptotic expansions for an RF when inter-event times are periodic. General bounds for an RF are discussed in Lorden [19] and Barlow and Proschan [20]. More recent development of these bounds can be found in

Politis Koutras [21]. For an introduction and review on warranty management and its connection with the renewal theory, the readers are referred to Blischke and Murthy [22] and Thomas and Rao [23].

LINEAR PROGRAMMING AND TWO-PERSON ZERO-SUM GAMES

PABLO ZAFRA
Department of Mathematics,
Kean University, Union,
New Jersey

From their inception, the theories underlying linear programming and two-person zero-sum games (also commonly referred to as *matrix games*) have been intertwined, especially with respect to the related primal-dual problems (see the section titled “Linear Programming” in this encyclopedia). The close relationship between these two seemingly disparate areas has been established first in 1947 when von Neumann pointed out that his minimax theorem is equivalent to the concept of duality in linear programming (LP), establishing the transformation of a matrix game into a pair of primal-dual LP problems [1]. Gale *et al.* [2] later illustrated the converse situation of transforming an LP problem into a symmetric game (i.e., a matrix game with skew-symmetric matrix), establishing the full equivalence between the two problems.

However, the relationship between the computational aspects for solving matrix games and linear programs has been one-way; we solve matrix games by transforming them into linear programming problems, but the use of game algorithms in the solution of linear programs is rare. To date, when one wants to solve a matrix game, it is easy and convenient to convert the game to a standard linear programming problem as discussed below, and then solve the resultant problem using a computer code based on the simplex or interior point methods.

TRANSFORMING MATRIX GAMES INTO LINEAR PROGRAMMING PROBLEMS

A two-person zero-sum game is represented by an $(m \times n)$ payoff matrix $A = (a_{ij})$, where

the entry a_{ij} represents the payment of column player P2 to the row player P1, should P1 choose row i as his move and should P2 choose column j as her move. It is clear that P1 would want to select the row that will maximize his potential payoff, while P2 would want to select the column that will minimize her payout. Note that, if a_{ij} is negative, then it is interpreted as P1's payment to P2 for the corresponding pair of strategies. This two-person game is called *zero-sum* because one player's gain is the other player's loss. The rows and columns of A are called *pure* (or *deterministic*) strategies that are available for the two players to choose.

If the maximizing player P1 selects row i , then his payoff is at least $\min_j a_{ij}$, while the minimizing player P2's payout would be at most $\max_i a_{ij}$ should she select column j . For this reason, P1 would select the pure strategy i that would make $\min_j a_{ij}$ as large as possible and, therefore, he is assured of winning at least $\max_i \min_j a_{ij}$. On the other hand, P2 would select the pure strategy j that would make $\max_i a_{ij}$ as small as possible to minimize her losses. Consequently, by doing this, P2 can keep P1 from winning no more than $\min_j \max_i a_{ij}$. It can be shown that $\max_i \min_j a_{ij} \leq \min_j \max_i a_{ij}$, that is, P1's maximin pure strategy is no more than P2's minimax pure strategy. If $\max_i \min_j a_{ij} = \min_j \max_i a_{ij} = v$ for some pair i and j , then the matrix game is said to have a saddlepoint (or equilibrium point) corresponding to the pair of optimal pure strategies i and j with the value of the game given by v . Both players should play the row and column associated with the saddlepoint, which assures P1 to win v and P2 to pay the same amount. As an equilibrium point, given what P2 is playing, any other choice for P1 lowers his opportunity to win at least v and, conversely, given what P1 is playing, any other choice for P2 raises P1's opportunity to win more than v .

However, not all matrix games can be played with an optimal pair of pure strategies. In fact, since the game is antagonistic in nature, fixing a pure strategy for P1 in advance when there is no saddle point is not a good move if P2 can “read” his mind. This is because P2 can always choose a pure strategy that would be favorable to her. In the same manner, if P1 can “read” P2’s mind/move in advance, then P1 can select his pure strategy that would be favorable to him. As a simple illustration that a predictable strategy is bad when there is no saddlepoint, consider the familiar rock-paper-scissors game. If one player fixes his/her move, say “rock,” and the other player can “read” this in advance, then this other player will certainly choose “paper” as his/her move for him/her to win the game. In this situation, both players’ interest is clearly best served if they choose their moves with some amount of randomness.

To do this, they will assign certain probabilities to choosing rows and columns for their strategies. For example, suppose P1 selects row i with probability x_i , and P2 selects column j with probability y_j . With these probabilities as components, the vectors $x = (x_1, \dots, x_m)^T$ and $y = (y_1, \dots, y_n)^T$, where $\sum_i x_i = \sum_j y_j = 1$ and $x_i, y_j \geq 0$, are called *randomized (mixed) strategies* for P1 and P2, respectively. Note that any mixed strategy with one of the components equal to 1 (and all others 0) is a *pure strategy*.

If P1 uses any mixed strategy x and P2 uses any mixed strategy y , the expected payoff to P1 from P2 for this pair of strategies is given by $E(x, y) = \sum_i \sum_j x_i a_{ij} y_j$ [3]. For any mixed strategy x that P1 chooses, P2’s interest is to choose her mixed strategy y that minimizes P1’s expected payoff. In this case, P1 can expect to receive at least $\min_y E(x, y)$, and therefore he would want to select his particular strategy x that will make this as large as possible. That is, his goal is to solve $\max_x \min_y E(x, y)$ for that strategy x . Similarly, for any mixed strategy y that P2 chooses, P1’s interest is to choose a mixed strategy x that maximizes his expected payoff. In this case, P2 can expect not to

lose more than $\max_x E(x, y)$, and therefore she would want to select her particular strategy y that will make this as small as possible. That is, her goal is to solve $\min_y \max_x E(x, y)$ for that strategy y . Von Neuman’s Minimax Theorem [4] states that there exists a pair of optimal mixed strategies (x, y) such that $\max_x \min_y E(x, y) = \min_y \max_x E(x, y)$; that is, the expected payoff for P1 is equal to the expected loss for P2. This common value is considered the value of the game (see **Saddlepoints and von Neumann Minimax Theorem**).

We now formulate the LP equivalence in regards to P1. His goal is to find a mixed strategy $x = (x_1, \dots, x_m)$ where $\sum_i x_i = 1, x_i \geq 0$ that will maximize $\min_y E(x, y)$. It can be shown that, for any given x , $\min_y E(x, y)$ is attained at some pure strategy j that P2 should choose; that is, $\min_y E(x, y) = \min_j \sum_i x_i a_{ij}$ [5]. Therefore, no matter what P2’s pure strategy selection is, P1 is assured of winning at least $\min_j \sum_i x_i a_{ij}$. Let v be a lower bound for each of the j summations, $\sum_i x_i a_{ij} \geq v$. Then P1’s goal is equivalent to maximizing v . We now have the LP problem formulation for P1 as given below (LP1)

$$\begin{aligned}
 & \max v \\
 & \text{s.t.} \\
 & a_{11}x_1 + a_{21}x_2 + \dots + a_{m1}x_m \geq v \quad (j = 1) \\
 & a_{12}x_1 + a_{22}x_2 + \dots + a_{m2}x_m \geq v \quad (j = 2) \\
 & \vdots \\
 & a_{1n}x_1 + a_{2n}x_2 + \dots + a_{mn}x_m \geq v \quad (j = n) \\
 & x_1 + \dots + x_m = 1 \\
 & x_i \geq 0.
 \end{aligned}$$

Note that each inequality corresponds to P2’s pure strategy with the indicated value in parenthesis.

Using analogous arguments above, let us now develop the LP formulation in regard to P2’s point of view. Her goal is to find a mixed strategy $y = (y_1, \dots, y_n)$ where $\sum_j y_j = 1, y_j \geq 0$ that will minimize

$\max_x E(x, y)$. It can also be shown that for any given y , $\max_x E(x, y)$ is attained at some pure strategy i that P1 should choose; that is, $\max_x E(x, y) = \max_i \sum_j a_{ij} y_j$ [5]. Therefore, no matter what P1's pure strategy selection is, P2's cost is no more than $\max_i \sum_j a_{ij} y_j$. Let u be an upper bound for each of the i summations, $\sum_j a_{ij} y_j \leq u$. Then P2's goal is equivalent to minimizing u . We now have the LP problem formulation for P2 as given below (LP2)

$$\begin{aligned} & \min u \\ & \text{s.t.} \\ & a_{11}y_1 + a_{12}y_2 + \cdots + a_{1n}y_n \leq u \quad (i = 1) \\ & a_{21}y_1 + a_{22}y_2 + \cdots + a_{2n}y_n \leq u \quad (i = 2) \\ & \vdots \\ & a_{m1}y_1 + a_{m2}y_2 + \cdots + a_{mn}y_n \leq u \quad (i = m) \\ & y_1 + \cdots + y_n = 1 \\ & y_j \geq 0. \end{aligned}$$

Here, each inequality corresponds to P1's pure strategy with the indicated value in parenthesis.

Observe that LP2 is the dual of the LP1 (primal) problem. Since von Neumann's Minimax Theorem guarantees that every matrix game has a solution, the primal-dual problems we formulated are both feasible and have optimal solutions. Suppose LP1 has optimal solution (x^*, v^*) , then it follows that P1's expected payoff is v^* if he selects his optimal mixed strategy x^* . Similarly, if LP2 has optimal solution (y^*, u^*) , then it follows that P2's expected cost is u^* if she selects her optimal mixed strategy y^* . The Duality Theorem of Linear Programming states that the primal-dual problems have the same optimal value for the objective functions [5]; that is, $v^* = u^*$. This remarkable fact that P1's optimal expected payoff of v^* is equal to P2's optimal expected cost of u^* (with the corresponding pair of optimal mixed strategies (x^*, y^*) for P1 and P2, respectively) is precisely what von Neumann's Theorem asserts as well, with the common expected payoff/cost

$v^* = u^*$ as the value of the game. Therefore, the minimax theorem and the duality theorem in LP are indeed equivalent (see **LP Duality and KKT Conditions for LP**).

Example 1. In the rock-paper-scissors game, the payoff matrix is given by

$$A = \begin{bmatrix} 0 & -1 & 1 \\ 1 & 0 & -1 \\ -1 & 1 & 0 \end{bmatrix},$$

where $i, j = 1$ (rock), 2 (paper), 3 (scissors).

One would quickly realize that any pair of pure strategies (i, j) where $i \neq j$ would not be favorable to the other player. As explained earlier, a predictable move in a game with no saddlepoint such as this one is bad. Let us now show that the rock-paper-scissors game has no saddlepoint. In finding the maximin and minimax pure strategies, we see that

P1's maximin pure strategy:

$$\begin{aligned} & \max_j \{\min_i a_{ij} = -1, \min_j a_{2j} = -1, \\ & \min_j a_{3j} = -1\} = -1 \end{aligned}$$

P2's minimax pure strategy:

$$\begin{aligned} & \min_i \{\max_j a_{i1} = 1, \max_j a_{i2} = 1, \\ & \max_j a_{i3} = 1\} = 1 \end{aligned}$$

Since maximin $\neq$ minimax, the game has no saddlepoint. Therefore, it would be in the best interests of both players to find their optimal mixed strategies instead. To do this, we now formulate the necessary primal-dual LP problems.

Primal LP.

$$\begin{aligned} & \max v \\ & \text{s.t.} \\ & x_2 - x_3 \geq v \\ & -x_1 + x_3 \geq v \\ & x_1 - x_2 \geq v \\ & x_1 + x_2 + x_3 = 1 \\ & x_i \geq 0. \end{aligned}$$

Dual LP.

$$\begin{aligned}
 &\min u \\
 &\text{s.t.} \\
 &\quad -y_2 + y_3 \leq u \\
 &\quad y_1 \quad -y_3 \leq u \\
 &\quad -y_1 + y_2 \leq u \\
 &\quad y_1 + y_2 + y_3 = 1 \\
 &\quad y_j \geq 0.
 \end{aligned}$$

The optimal solutions for the primal-dual problems are obtained with $v^* = u^* = 0$, $x^* = (1/3, 1/3, 1/3)$, and $y^* = (1/3, 1/3, 1/3)$. Note that both players have identical optimal mixed strategies with game value of zero, so that in the long run, by uniformly but randomly mixing his choices, P1's expected payoff will be zero regardless of what P2's chosen strategy is (and vice versa). These characteristics (identical optimal mixed strategies with game value zero) are always true of symmetric games. A symmetric game is a matrix game with skew-symmetric payoff matrix, that is, $A = -A^T$. Observe that the rock-paper-scissors payoff matrix is skew-symmetric.

Example 2. Consider the following payoff matrix:

$$A = \begin{bmatrix} 1 & 5 & 0 & 2 \\ 2 & -1 & 3 & 3 \\ 4 & 2 & -1 & 0 \end{bmatrix}.$$

Let us first find the maximin and minimax pure strategies for both players to determine whether a saddlepoint exists. We see that row player P1 can select among the three pure strategies available, while column player P2 can select among the four pure strategies available, as shown

$$\begin{aligned}
 &\text{P1's maximin pure strategy: } \max_j \{\min_j a_{1j} = 0, \min_j a_{2j} = -1, \min_j a_{3j} = -1\} = 0 \\
 &\text{P2's minimax pure strategy: } \min_i \{\max_i a_{i1} = 4, \max_i a_{i2} = 5, \max_i a_{i3} = 3, \max_i a_{i4} = 3\} = 3.
 \end{aligned}$$

Since there is no saddle point (maximin $\neq$ minimax), let us now formulate the associated primal-dual LP problems to find the optimal mixed strategies.

Primal LP.

$$\begin{aligned}
 &\max v \\
 &\text{s.t.} \\
 &\quad x_1 + 2x_2 + 4x_3 \geq v \\
 &\quad 5x_1 - x_2 + 2x_3 \geq v \\
 &\quad 3x_2 - x_3 \geq v \\
 &\quad 2x_1 + 3x_2 \geq v \\
 &\quad x_1 + x_2 + x_3 = 1 \\
 &\quad x_i \geq 0.
 \end{aligned}$$

Dual LP.

$$\begin{aligned}
 &\min u \\
 &\text{s.t.} \\
 &\quad y_1 + 5y_2 \quad + 2y_4 \leq u \\
 &\quad 2y_1 - y_2 + 3y_3 + 3y_4 \leq u \\
 &\quad 4y_1 + 2y_2 - y_3 \leq u \\
 &\quad y_1 + y_2 + y_3 + y_4 = 1 \\
 &\quad y_j \geq 0.
 \end{aligned}$$

The optimal solutions for the primal-dual problems are obtained with $v^* = u^* = 13/8$, $x^* = (17/40, 11/20, 1/40)$, and $y^* = (3/8, 1/4, 3/8, 0)$. If both players play these optimal mixed strategies, P1 can expect to win, on average, $13/8$ units. P2 under the same assumption can expect to lose, on average, $13/8$ units. Note that $y_4 = 0$ in P2's optimal strategy, which indicates that the respective column (column 4) can be removed from the payoff matrix with no effect on the game. If we actually realized at the start that column 3 dominates over column 4 in our payoff matrix, then we can deduce that P2 would never select column 4 as her strategy. Therefore, we could intuitively discard column 4 immediately before solving the game.

Example 3. Our next example shows that the strength of LP solution comes out when a nondominated strategy is not used by a player. Consider the following payoff matrix:

$$A = \begin{bmatrix} 1 & 5 & 0 & -7 \\ 2 & -1 & 3 & 11 \\ 4 & 2 & -1 & 7 \end{bmatrix}.$$

Note that column 4 has been replaced in Example 2, and as a result, column 3 (or any other column) no longer dominates column 4. However, it turns out from the LP solution below that this “nondominated” strategy is still not used by P2. First, the maximin and minimax pure strategies for both players are calculated below to determine if saddlepoint exists

$$\text{P1's maximin pure strategy: } \max_j \{\min_j a_{1j} = -1, \min_j a_{2j} = -1, \min_j a_{3j} = -1\} = -1$$

$$\text{P2's minimax pure strategy: } \min_i \{\max_i a_{i1} = 4, \max_i a_{i2} = 5, \max_i a_{i3} = 3, \max_i a_{i4} = 12\} = 3$$

Since there is no saddle point (maximin $\neq$ minimax), the associated primal-dual LP problems are formulated below to find the optimal mixed strategies.

Primal LP.

$$\begin{aligned} \max v \\ \text{s.t.} \\ x_1 + 2x_2 + 4x_3 &\geq v \\ 5x_1 - x_2 + 2x_3 &\geq v \\ 3x_2 - x_3 &\geq v \\ -7x_1 + 11x_2 + 7x_3 &\geq v \\ x_1 + x_2 + x_3 &= 1 \\ x_i &\geq 0. \end{aligned}$$

Dual LP.

$$\begin{aligned} \min u \\ \text{s.t.} \\ y_1 + 5y_2 - 7y_4 &\leq u \\ 2y_1 - y_2 + 3y_3 + 11y_4 &\leq u \\ 4y_1 + 2y_2 - y_3 + 7y_4 &\leq u \\ y_1 + y_2 + y_3 + y_4 &= 1 \\ y_j &\geq 0. \end{aligned}$$

The optimal solutions for the primal-dual problems are obtained with $v^* = u^* = 13/8$, $x^* = (17/40, 11/20, 1/40)$, and $y^* = (3/8, 1/4, 3/8, 0)$. These are identical results found in Example 2, which indicates that column 4 could have been discarded at the onset with no effect on the game. However, unlike Example 2, this is not so obvious since none of the other columns dominate column 4. Moreover, as what seems to be a “nondominated” strategy, it is still somewhat surprising that P2 would never play it. The reason is that column 4 is actually dominated by a linear combination of the other columns,

$$\text{namely, } 3A_1 - 2A_2 + A_3 = \begin{bmatrix} -7 \\ 11 \\ 7 \end{bmatrix}, \text{ where}$$

A_j is the j th column of A . This “hidden” domination is nonetheless revealed through the LP solution. To get the coefficients of the linear combination, simply identify the ordered basic variables from the optimal simplex tableau (which in this case are y_1 , y_2 , and y_3) to construct the “basis” matrix B , by using the corresponding columns of the payoff matrix A associated with the ordered basic variables. The product $B^{-1}A_4 = [A_1 \ A_2 \ A_3]^{-1}A_4 = \begin{pmatrix} 3 \\ -2 \\ 1 \end{pmatrix}$ will then provide the coefficients.

In general, the product $B^{-1}A_k$ gives the coefficients of the linear combination for any nonbasic variable (whose index is k) in terms of the ordered basic variables.

REDUCTION OF LINEAR PROGRAMMING PROBLEMS INTO MATRIX GAMES

We now consider the converse problem of converting linear programming problems into matrix games. More specifically, we will discuss how to construct the symmetric game that will be associated with a given primal LP problem in three different forms: normal, standard, and mixed. Recall that a symmetric game is a matrix game with skew-symmetric payoff matrix.

Normal LP

We begin by analyzing the following *normal* form of a primal-dual pair of a linear programming problem in matrix-vector notation

Primal LP.

$$\begin{aligned} \min \quad & z = c^T y \\ \text{s.t.} \quad & \\ & Ay \geq b \\ & y \geq 0. \end{aligned}$$

Dual LP.

$$\begin{aligned} \max \quad & w = b^T x \\ \text{s.t.} \quad & \\ & A^T x \leq c \\ & x \geq 0. \end{aligned}$$

In both problems, c is $(n \times 1)$ vector, x is $(m \times 1)$ vector, y is $(n \times 1)$ vector, b is $(m \times 1)$ vector, and A is an $(m \times n)$ general matrix.

The symmetric game equivalent to the primal-dual problems above is given by the $(m+n+1) \times (m+n+1)$ block skew-symmetric payoff matrix [1]

$$S = \begin{bmatrix} 0 & -A & b \\ A^T & 0 & -c \\ -b^T & c^T & 0 \end{bmatrix}.$$

Here, the block matrix 0 indicates a matrix of appropriate dimensions, all of whose components are zero. Observe that S can be

constructed completely from the given primal LP problem. The associated dual problem need not be formulated at all.

Let us now examine how this matrix S is related to the primal-dual LP problems. Let the block $m+n+1$ vector $(x; y; \lambda)^T$ represent the mixed strategy vector for P2. As S is skew-symmetric, the matrix game has, of course, a value of zero and, therefore, P2's goal is to find an optimal strategy that will satisfy the inequality

$$\begin{bmatrix} 0 & -A & b \\ A^T & 0 & -c \\ -b^T & c^T & 0 \end{bmatrix} \begin{bmatrix} x \\ y \\ \lambda \end{bmatrix} \leq 0. \quad (1)$$

Here, the right-hand side is a column zero vector with $m+n+1$ components. Moreover, from the properties of symmetric games, an optimal mixed strategy for P2 is also the optimal strategy for P1.

To see that solving inequality (1) is equivalent to solving the associated primal-dual LP problems, suppose the block vector $(x; y; \lambda)^T$ is an optimal mixed strategy for both players. The optimal primal and dual solutions to the LP can then be calculated as follows:

$$\begin{aligned} y^{\text{opt}} &= y/\lambda \\ x^{\text{opt}} &= x/\lambda \end{aligned} \quad (2)$$

provided, of course, that $\lambda \neq 0$. With these calculations of the LP primal-dual solutions, one can perform the block matrix-vector multiplication in the inequality (1) above, and quickly realize that satisfying the above inequality does indeed correspond to satisfying the primal-dual LP constraints including the dual relationship between the objective functions.

Although a solution to S always exists (as is true of any matrix game), the associated LP, however, may not have any solution. As seen from Equation (2), this happens when $\lambda = 0$ in the optimal mixed strategy solution.

The transformation procedure described above can be adapted easily when the primal-dual LP problems are reversed; namely, when the primal LP being considered is a maximization problem with " $\leq$ " constraints and the dual LP is the corresponding minimization problem with " $\geq$ " constraints. In this

case, the resulting skew-symmetric matrix is given by

$$S_1 = \begin{bmatrix} 0 & A^T & -c \\ -A & 0 & b \\ c^T & -b^T & 0 \end{bmatrix}$$

with the block $m + n + 1$ vector $(y; x; \lambda)^T$ representing the optimal mixed strategy vector for both players. The solutions for the associated primal-dual LP is calculated in an analogous manner as before.

Once the skew-symmetric matrix is formed, an iterative procedure such as Brown's Fictitious Play Method [6] can be used to solve the game, and hence the associated LP (see **Fictitious Play Algorithm**). However, current wisdom dictates that solving an LP using either the simplex method or any of the interior point methods would be vastly superior compared to any game-theoretic computational methods. A hybrid approach might be more effective though, particularly for solving large games. Gass and Zafra [7] described initial experiments with encouraging results in which their Modified Fictitious Play Method can be combined with simplex and interior points to aid in the solution of LP problems.

Example 4. Consider the following LP problem:

$$\begin{aligned} \min z &= 40y_1 + 25y_2 + 10y_3 \\ \text{s.t.} \\ y_1 + 5y_2 &\geq 4 \\ 2y_1 - y_2 + y_3 &\geq 8 \\ y_j &\geq 0. \end{aligned}$$

The associated dual LP is given by

$$\begin{aligned} \max w &= 4x_1 + 8x_2 \\ \text{s.t.} \\ x_1 + 2x_2 &\leq 40 \\ 5x_1 - x_2 &\leq 25 \\ x_2 &\leq 10 \\ x_i &\geq 0. \end{aligned}$$

From the given primal problem, we see that

$$A = \begin{bmatrix} 1 & 5 & 0 \\ 2 & -1 & 1 \end{bmatrix}, b = \begin{bmatrix} 4 \\ 8 \end{bmatrix},$$

and $c = \begin{bmatrix} 40 \\ 25 \\ 10 \end{bmatrix}.$

We use this information to construct the skew-symmetric matrix for the corresponding symmetric game as shown below

$$S = \begin{bmatrix} 0 & 0 & -1 & -5 & 0 & 4 \\ 0 & 0 & -2 & 1 & -1 & 8 \\ 1 & 2 & 0 & 0 & 0 & -40 \\ 5 & -1 & 0 & 0 & 0 & -25 \\ 0 & 1 & 0 & 0 & 0 & -10 \\ -4 & -8 & 10 & 25 & 10 & 0 \end{bmatrix}$$

Standard LP

We describe next how to transform primal LP problems with equality constraints (commonly referred to as *LP in standard form*) into a symmetric game. The basic idea is to first transform the given primal LP problem with minimizing objective function into normal form (i.e., with constraints consisting only of " $\geq$ " inequalities).

Let us now consider the following primal-dual pair of a linear programming problem, with the primal problem given in standard form

Primal LP.

$$\begin{aligned} \min \quad z &= c^T y \\ \text{s.t.} \\ Ay &= b \\ y &\geq 0. \end{aligned}$$

Dual LP.

$$\begin{aligned} \max \quad w &= b^T x \\ \text{s.t.} \\ A^T x &\leq c \\ x, &\text{ unrestricted.} \end{aligned}$$

Here, A, c, b, x , and y have the same dimensions as noted in the “normal” case.

Let us now transform the primal LP into normal form and let $x = x_1 - x_2$. By duality theory of linear programming, we have the equivalent primal-dual pair as follows:

Primal LP.

$$\begin{aligned} \min \quad & z = c^T y \\ \text{s.t.} \quad & \\ & Ay \geq b \\ & -Ay \geq -b \\ & y \geq 0. \end{aligned}$$

Dual LP.

$$\begin{aligned} \max \quad & w = b^T x_1 - b^T x_2 \\ \text{s.t.} \quad & \\ & A^T x_1 - A^T x_2 \leq c \\ & x_1, x_2 \geq 0. \end{aligned}$$

The corresponding $(2m + n + 1) \times (2m + n + 1)$ skew-symmetric game matrix can now be constructed as follows:

$$S_2 = \begin{bmatrix} 0 & 0 & -A & b \\ 0 & 0 & A & -b \\ A^T & -A^T & 0 & -c \\ -b^T & b^T & c^T & 0 \end{bmatrix}.$$

As in S , the block matrix 0 indicates a matrix of appropriate dimensions, all of whose components are zero. Observe that the skew-symmetric matrix is enlarged by additional m rows and m columns due to the “splitting” of the vector x in terms of two vectors x_1 and x_2 . Again, observe that the matrix S_2 can be constructed using only the information from the given primal LP problem.

Now, if the block $2m + n + 1$ vector $(x_1; x_2; y; \lambda)$ is an optimal strategy for S_2 , then the associated LP problem has the optimal primal-dual solution

$$\begin{aligned} y^{\text{opt}} &= y/\lambda \\ x^{\text{opt}} &= (x_1 - x_2)/\lambda \end{aligned}$$

provided again that $\lambda \neq 0$.

Example 5. Consider the primal LP problem in Example 4 where we now change the inequalities in the constraints into equations. The new linear problem is shown below

$$\begin{aligned} \min \quad & z = 40y_1 + 25y_2 + 10y_3 \\ \text{s.t.} \quad & \\ & y_1 + 5y_2 = 4 \\ & 2y_1 - y_2 + y_3 = 8 \\ & y_j \geq 0. \end{aligned}$$

As in Example 4, we see that $A = \begin{bmatrix} 1 & 5 & 0 \\ 2 & -1 & 1 \end{bmatrix}$, $b = \begin{bmatrix} 4 \\ 8 \end{bmatrix}$, and $c = \begin{bmatrix} 40 \\ 25 \\ 10 \end{bmatrix}$. However, the skew-symmetric matrix for this new problem is a larger matrix S_2 as shown

$$S_2 = \begin{bmatrix} 0 & 0 & 0 & 0 & -1 & -5 & 0 & 4 \\ 0 & 0 & 0 & 0 & -2 & 1 & -1 & 8 \\ 0 & 0 & 0 & 0 & 1 & 5 & 0 & -4 \\ 0 & 0 & 0 & 0 & 2 & -1 & 1 & -8 \\ 1 & 2 & -1 & -2 & 0 & 0 & 0 & -40 \\ 5 & -1 & -5 & 1 & 0 & 0 & 0 & -25 \\ 0 & 1 & 0 & -1 & 0 & 0 & 0 & -10 \\ -4 & -8 & 4 & 8 & 40 & 25 & 10 & 0 \end{bmatrix}$$

Mixed LP

Finally, we describe the skew-symmetric matrix associated with minimization LP problems having mixed constraints (equations and inequalities). We apply the same idea introduced in the preceding case and convert the LP into normal form. To start, we express each equality constraints equivalently into two inequalities of the form “ $\geq$ ” and “ $\leq$ ”. In addition, each “ $\leq$ ” constraint is also transformed into “ $\geq$ ” constraint, as was done in the standard LP case. In an analogous manner that S_2 was constructed, the resulting skew-symmetric for the “mixed” LP is given by

$$S_3 = \begin{bmatrix} 0 & 0 & -A & b \\ 0 & 0 & \tilde{A} & -\tilde{b} \\ A^T & -\tilde{A}^T & 0 & -c \\ -b^T & \tilde{b}^T & c^T & 0 \end{bmatrix},$$

where the matrix $\tilde{A}$ and vector $\tilde{b}$ are associated with “ $\leq$ ” inequalities arising from the equations (that were transformed later into “ $\geq$ ”), while the matrix A consists of the elements associated with the regular “ $\geq$ ” inequalities and the original “ $\leq$ ” inequalities (that were transformed later into “ $\geq$ ”). As in S_2 , the block matrix 0 indicates a matrix of appropriate dimensions, all of whose components are zero. Moreover, as in the other previous cases, observe that the matrix S_3 can be constructed using only the information from the given primal LP problem; the corresponding dual problem need not be formulated.

One can quickly notice the similarity of the structures between the matrices S_2 and S_3 . However, on closer inspection, S_3 is more similar to the matrix S of the normal primal LP as can be seen in Example 6 below. This is due to the fact that the mixed constraints were all transformed into “ $\geq$ ” inequalities, resulting thereby in a normal form of the LP problem. The similarity between S and S_3 ends here, because although the optimal mixed strategy in regards to both game matrices have the same form, namely, the block vector $(x; y; \lambda)^T$, the number of components of the vector x in the case of S_3 is not predetermined (recall that in S , x has m components). It depends on how many equations are present in the constraints of the given primal LP problem (each equation adds an additional component to the vector x). To be more specific, if A is $(m \times n)$ and there are k equations among the m constraints, then the vector x will have $m + k$ number of components. Since the number of components of the vector y is known (which is n , of course), then the optimal primal solution to the LP is easily calculated as in S

$$y^{\text{opt}} = y/\lambda,$$

provided again that $\lambda \neq 0$. If needed, the optimal solutions to the corresponding dual LP has to be manually determined, but it is not difficult to do so.

Example 6. Consider the following LP problem with mixed types of constraints:

$$\begin{aligned} \min z &= 40y_1 + 25y_2 + 10y_3 \\ \text{s.t.} \\ y_1 &\quad - y_3 \geq 3 \\ y_1 + 5y_2 &\leq 4 \\ 2y_1 - y_2 + y_3 &= 8 \\ y_j &\geq 0. \end{aligned}$$

Applying the transformation with regard to the equality and “ $\leq$ ” constraints, we obtain the normal form of the primal LP

$$\begin{aligned} \min z &= 40y_1 + 25y_2 + 10y_3 \\ \text{s.t.} \\ y_1 &\quad - y_3 \geq 3 \\ -y_1 - 5y_2 &\geq 4 \\ 2y_1 - y_2 + y_3 &\geq 8 \\ -2y_1 + y_2 - y_3 &\geq -8 \\ y_j &\geq 0. \end{aligned}$$

We see that

$$A = \begin{bmatrix} 1 & 0 & -1 \\ -1 & -5 & 0 \\ 2 & -1 & 1 \end{bmatrix}, \quad \tilde{A} = \begin{bmatrix} 2 & -1 & 1 \end{bmatrix},$$

$$b = \begin{bmatrix} 3 \\ 4 \\ 8 \end{bmatrix}, \quad \tilde{b} = [8], \quad \text{and } c = \begin{bmatrix} 40 \\ 25 \\ 10 \end{bmatrix}.$$

Therefore, the skew-symmetric matrix for the equivalent game is as given below

$$S_3 = \begin{bmatrix} 0 & 0 & 0 & 0 & -1 & 0 & 1 & 3 \\ 0 & 0 & 0 & 0 & 1 & 5 & 0 & 4 \\ 0 & 0 & 0 & 0 & -2 & 1 & -1 & 8 \\ 0 & 0 & 0 & 0 & 2 & -1 & 1 & -8 \\ 1 & -1 & 2 & -2 & 0 & 0 & 0 & -40 \\ 0 & -5 & -1 & 1 & 0 & 0 & 0 & -25 \\ -1 & 0 & 1 & -1 & 0 & 0 & 0 & -10 \\ -3 & -4 & -8 & 8 & 40 & 25 & 10 & 0 \end{bmatrix}$$

For this game matrix, the block vector for the mixed strategy is $(x; y; \lambda)^T = (x_1, x_2, x_3, x_4, y_1, y_2, y_3, \lambda)^T$. Note that the vector x has $4(3 + 1)$ components: one more than

the number of rows of A in the given LP, because there is one equation present in the constraints.

CONCLUDING REMARKS

The equivalence between two-person zero-sum games and linear programming was established in the late 1940s and early 1950s by Dantzig, Gale Kuhn, von Neuman, Tucker and others. When the concept of duality in LP proved to be equivalent to Von Neumann's game theory duality in his Minimax Theorem, which was published earlier in 1928. As discussed in the section titled "Transforming Matrix Games into Linear Programming Problems," this remarkable result stems from the transformation of a matrix game into a pair of primal-dual LP problems. Gale *et al.* [2] later illustrated the converse situation of transforming an LP problem into a symmetric game (i.e., a matrix game with skew-symmetric matrix), establishing the full equivalence between matrix games and LP problems.

Although a number of game-theoretic methods for solving matrix games have been developed early, such as Brown's fictitious play method [6], Brown and von Neumann's differential equation approach [8], and the numerical method of von Neumann [9], it has long been recognized that an efficient way to solve most matrix games is by converting them to equivalent linear programming problems [10]. The resultant LP problem is then solved using a mathematical programming software based on either the simplex or interior point methods. However, faster game-theoretic methods and algorithms are still being developed to solve matrix games directly, such as modifications to the fictitious play method [11,12], fast algorithms to determine whether there is a saddlepoint [13,14], sublinear-time approximation algorithms [15], sequential methods in finding the equilibria [16], iterated technique in finding Nash equilibrium [17], and first-order algorithms that match the complexity of interior-point methods and use less memory [18].

As to the relationship itself between matrix games and linear programming, a

new research trend seems to be focusing on fuzzy linear programs and fuzzy payoffs [19,20]. Interested readers are referred to Nishizaki and Sakawa [21] or Bector and Chandra [22] for an overview of this evolving facet in the study of linear programming and two-person zero-sum games.

LINEAR PROGRAMMING PROJECTION ALGORITHMS

YURY EVTUSHENKO
ALEXANDER GOLIKOV
Computing Centre of Russian
Academy of Sciences, Moscow,
Russia

Large-scale LP (linear programming) problems usually have more than one solution. Techniques such as the simplex methods and interior point methods make it possible to obtain different solutions in the case of nonuniqueness. For example, the simplex method yields a solution belonging to a vertex of polyhedron. Some variants of the interior point method converge to a solution satisfying the strict complementary slackness condition.

LP projection method is close to the quadratic penalty function method and to the modified Lagrangian function method. This method yields the exact projection of a given point on the solution set of primal LP problem as a result of the single unconstrained maximization of an auxiliary piecewise quadratic concave function for any sufficiently large values of the penalty parameter. A generalized Newton method with a stepsize chosen using Armijo's rule was used for unconstrained maximization. The proof of globally convergent finitely terminating generalized Newton method for piecewise quadratic function was given in Mangasarian [1] and Kanzow *et al.* [2]. LP projection method solves LP problems with a very large ($\approx 10^7$) number of variables and moderate ($\approx 10^5$) number of constraints.

In a similar way, the exact projection of a given point on the solution set of the dual LP problem can be obtained by nonnegative constrained maximization of auxiliary quadratic function for sufficiently large but finite values of the penalty parameter.

Consider the primal linear program in the standard form

$$f_* = \min_{x \in X} c^\top x, X = \{x \in R^n : Ax = b, x \geq 0_n\} \quad (P)$$

together with its dual

$$f_* = \max_{u \in U} b^\top u, U = \{u \in R^m : A^\top u \leq c\}, \quad (D)$$

where $A \in R^{m \times n}$, $c \in R^n$, and $b \in R^m$ are given, x is a primal variable and u is a dual variable, 0_i denotes the i -dimensional zero vector.

Everywhere we assume that the solution set X_* of the primal problem (P) is nonempty, and hence the solution set U_* of the dual problem (D) is also nonempty.

Consider the problems of finding the least 2-norm projection $\hat{x}_*$ of the point $\hat{x}$ on the solution set X_* and the least 2-norm projection $\hat{u}_*$ of the point $\hat{u}$ on the solution set U_* :

$$\frac{1}{2} \|\hat{x}_* - \hat{x}\|^2 = \min_{x \in X_*} \frac{1}{2} \|x - \hat{x}\|^2,$$

$$X_* = \{x \in R^n : Ax = b, c^\top x = f_*, x \geq 0_n\}, \quad (1)$$

$$\frac{1}{2} \|\hat{u}_* - \hat{u}\|^2 = \min_{u \in U_*} \frac{1}{2} \|u - \hat{u}\|^2,$$

$$U_* = \{u \in R^m : A^\top u \leq c, b^\top u = f_*\}. \quad (2)$$

Here, the Euclidian norm of vectors is used, and f_* is an *a priori* unknown optimal value of the objective function of the original LP problems (P) and (D).

Let us introduce the Lagrange functions for these problems:

$$L^1(x, p, \beta) = \frac{1}{2} \|x - \hat{x}\|^2 + p^\top (b - Ax) + \beta(c^\top x - f_*),$$

$$L^2(u, y, \alpha) = \frac{1}{2} \|u - \hat{u}\|^2 + y^\top (A^\top u - c) + \alpha(f_* - b^\top u).$$

Here, $p \in R^m$, $\beta \in R^1$, and $y \in R_+^n$, $\alpha \in R^1$ are Lagrange multipliers for problems (1) and (2), respectively.

The problems dual to problems (1) and (2) have the forms

$$\max_{p \in R^m} \min_{\beta \in R^1} L^1(x, p, \beta), \quad (3)$$

$$\max_{y \in R_+^n} \min_{\alpha \in R^1} L^2(u, y, \alpha). \quad (4)$$

The solutions of the inner minimization problems in Equations (3) and (4) have the following forms, respectively:

$$x = (\hat{x} - A^\top p - \beta c)_+, \quad (5)$$

$$u = \hat{u} + \alpha b - Ay, \quad (6)$$

where a_+ denotes the vector a with all negative components replaced by zeros.

Substituting Equation (5) into the Lagrange function $L^1(x, p, \beta)$ and Equation (6) into the Lagrange function $L^2(u, y, \alpha)$, we obtain the dual functions of problems (3) and (6), respectively:

$$\begin{aligned} \hat{L}^1(p, \beta) &= b^\top p - \frac{1}{2} \|\hat{x} + A^\top p - \beta c\|_+^2 \\ &\quad - \beta f_* + \frac{1}{2} \|\hat{x}\|^2, \\ \hat{L}^2(y, \alpha) &= -c^\top y - \hat{u}^\top (\alpha b - Ay) \\ &\quad - \frac{1}{2} \|\alpha b - Ay\|^2 + \alpha f_*. \end{aligned}$$

The function $\hat{L}^1(p, \beta)$ is concave, piecewise quadratic, and continuously differentiable in variables p and β . The function $\hat{L}^2(y, \alpha)$ is concave, quadratic, and twice continuously differentiable in both variables.

Dual problems (3) and (4) are reduced to the outer maximization problems, respectively:

$$\max_{p \in R^m} \hat{L}^1(p, \beta), \quad (7)$$

$$\max_{y \in R_+^n} \hat{L}^2(y, \alpha). \quad (8)$$

Solving problem (7), we find optimal p and β . Substituting them into Equation (5), we

obtain $\hat{x}_*$, which is the projection of the point $\hat{x}$ on the solution set of the primal LP problem (P).

Solving problem (8), we find optimal y and α . Substituting them into Equation (6), we obtain $\hat{u}_*$, which is the projection of the point $\hat{u}$ on the solution set of the dual LP problem (D).

Unfortunately, maximization problems (7) and (8) contain an *a priori* unknown value f_* , which is the optimal value of the objective function of the original LP problem. However, these problems can be simplified by eliminating this difficulty. For this purpose, the following simplified unconstrained maximization problem is solved instead of problem (7):

$$\begin{aligned} \max_{p \in R^m} S^1(p, \beta, \hat{x}), \text{ where } S^1(p, \beta, \hat{x}) \\ = b^\top p - \frac{1}{2} \|\hat{x} + A^\top p - \beta c\|_+^2. \end{aligned} \quad (9)$$

Here the scalar β is fixed.

Instead of problem (8), the following simplified maximization problem on the positive orthant is solved:

$$\begin{aligned} \max_{y \in R_+^n} S^2(y, \alpha, \hat{u}), \text{ where } S^2(y, \alpha, \hat{u}) \\ = -c^\top y + \hat{u}^\top Ay - \frac{1}{2} \|\alpha b - Ay\|^2. \end{aligned} \quad (10)$$

Here the scalar α is also fixed.

Let us first consider problem (9) and its relation to the primal LP problem (P). Note that, in contrast to problem (1), dual problem (7) has many solutions. Naturally, the question that arises is of finding the minimal value β_* of the Lagrange multiplier β among all solutions of problem (7). Once such β_* is found, one can fix $\beta \geq \beta_*$ in dual problem (7) and maximize the dual function $\hat{L}^1(p, \beta)$ only with respect to variable p , that is, solve problem (9). In this case, the pair $[p, \beta]$ is a solution to problem (7), and the triplet $[\hat{x}_*, p, \beta]$ is a saddle point of problem (1), where the projection $\hat{x}_*$ of the point $\hat{x}$ on the solution set X_* is defined by problem (5).

Theorem 1 [3]. *There exists β_* such that for all $\beta \geq \beta_*$ the unique least 2-norm projection $\hat{x}_*$ of a point $\hat{x}$ on X_* is given by*

$$\hat{x}_* = (\hat{x} + A^\top p(\beta) - \beta c)_+,$$

where $p(\beta)$ is a maximizer of $S^1(p, \beta, \hat{x})$ in problem (9).

Theorem 1 makes it possible to replace problem (7), which contains an *a priori* unknown value f_* , by problem (9), which involves the half-interval $[\beta_*, +\infty]$ instead of this value. This essentially simplifies the calculations. Note that the value β_* may be negative. This occurs when the projection of the point $\hat{x}$ on the solution set X_* coincides with the projection of this point on the feasible set X . The estimation of the threshold value β_* is given in Golikov and Evtushenko [3,5].

The next theorem tells us that a solution to problem (D) can be obtained from the single unconstrained maximization problem (9) if a point $\hat{x}_* \in X_*$ is found according to Theorem 1.

Theorem 2 [3]. *For all $\beta > 0$ and all $\hat{x} = x_* \in X_*$ an exact solution to dual problem (D) is given by $u_* = p(\beta)/\beta$, where $p(\beta)$ is a solution to the unconstrained maximization problem (9).*

To solve the primal and dual LP problems simultaneously, one can use the following iterative process:

$$p_{s+1} \in \arg \max_{p \in R^m} \left\{ b^\top p - \frac{1}{2} \| (x_s + A^\top p - \beta c)_+ \|^2 \right\} \quad (11)$$

$$x_{s+1} = (x_s + A^\top p_{s+1} - \beta c)_+, \quad (12)$$

where x_0 is an arbitrary starting point.

Theorem 3 [3]. *For all $\beta > 0$ and for arbitrary starting point x_0 , the iterative process (11)–(12) converges to $x_* \in X_*$ in a finite number of iterations ω . The formula $u_* = p_{\omega+1}/\beta$ provides an exact solution to the dual problem (D).*

Iterative process (11,12) is finite. It gives an exact solution to the primal problem (P) and the exact solution to the dual problem (D). Note that one can use this method even when one is unaware of the threshold value β_* . However, if the chosen coefficient is less than the threshold value, then this method, in a finite number of steps, yields some solution x_* to the primal problem (P) which is not a projection of the starting point x_0 on the solution set X_* . Note that $x_\omega = x_* \in X_*$ is the projection of the point $x_{\omega-1}$ on X_* .

The subsequent theorems are similar to Theorems 1–3.

Theorem 4 [4]. *There exists α_* such that for all $\alpha \geq \alpha_*$ the unique least 2-norm projection $\hat{u}_*$ of a point $\hat{u}$ on U_* is given by*

$$\hat{u}_* = \hat{u} + \alpha b - Ay(\alpha),$$

where $y(\alpha)$ is a point maximizing $S^2(y, \alpha, \hat{u})$ on R_+^n .

The estimation of the threshold value β_* is given in Evtushenko *et al.* [4].

Theorem 5 [4]. *For all $\alpha > 0$ and all $\hat{u} = u_* \in U_*$ an exact solution to primal problem (P) is given by $u_* = y(\alpha)/\alpha$, where $y(\alpha)$ is a point maximizing $S^2(y, \alpha, u_*)$ on R_+^n .*

To solve the primal and dual LP problems simultaneously, one can use the following iterative process:

$$y_{s+1} \in \arg \max_{y \in R_+^n} \left\{ -c^\top y + u_s^\top Ay - \frac{1}{2} \|\alpha b - Ay\|^2 \right\}, \quad (13)$$

$$u_{s+1} = u_s + \alpha b - Ay_{s+1}. \quad (14)$$

Theorem 6 [4]. *For all $\alpha > 0$ and for arbitrary starting point u_0 , the iterative process (13)–(14) converges to $u_* \in U_*$ in a finite number of iterations v . The formula $x_* = y_{v+1}/\alpha$ provides an exact solution to primal LP problem (P).*

Note that $u_* \in U_*$ is the projection of the point u_{v-1} on the solution set U_* of the problem (D).

The unconstrained maximization in Equations (9) and (11) can be performed by any method, for example, by the conjugate gradient method. However, the generalized Newton method [1] turns out to be much more efficient.

The objective function $S^1(p, \beta, \hat{x})$ of problems (9) is concave, piecewise quadratic, and differentiable. The ordinary Hessian does not exist for this function because the gradient

$$\frac{\partial}{\partial p} S^1(p, \beta, \hat{x}) = b - A(\hat{x} + A^\top p - \beta c)_+.$$

is not differentiable. However, for this function, one can define the generalized Hessian matrix, which is an $m \times m$ symmetric negative semidefinite matrix of the form

$$\frac{\partial^2}{\partial p^2} S^1(p, \beta, \hat{x}) = -AD(z)A^\top.$$

Here, $D(z)$ denotes the $n \times n$ diagonal matrix whose i th diagonal entry z^i is equal to 1 if $(\hat{x} + A^\top p - \beta c)^i > 0$ and z^i is equal to zero if $(\hat{x} + A^\top p - \beta c)^i \leq 0$ ($i = 1, 2, \dots, n$). The generalized Hessian matrix may be singular. Therefore, we use the following generalized Newton method:

$$p_{s+1} = p_s - \mu \left[\frac{\partial^2}{\partial p^2} S^1(p, \beta, \hat{x}) - \delta I_m \right]^{-1} S_p(p, \beta, \hat{x}),$$

where δ is a small positive number (typically $\delta = 10^{-4}$), I_m is the identity matrix of size $m \times m$, and μ is a stepsize chosen using Armijo's rule.

Unfortunately the generalized Newton method cannot be applied to the nonnegativity constrained maximization problem (10) directly. By incorporating the nonnegativity constraint $y \geq 0_n$ into the objective function of problem (10) as a penalty term, we have the unconstrained maximization problem

$$\max_{y \in R^n} \left\{ -c^\top y + \hat{u}^\top A y - \frac{1}{2} \|\alpha b - A y\|^2 - \frac{\tau}{2} \|(-y)_+\|^2 \right\},$$

where $\tau > 0$ is a penalty parameter. In this case, we obtained the optimal solution y only in limit as $\tau \rightarrow +\infty$. This property complicates the computation. There exists a very simple way to overcome this shortcoming.

Let a vector $w \in R^{m+n}$ consist of two vectors $w^\top = [u^\top, v^\top]$, where $u \in R^m, v \in R^n$. Consider the following LP problem

$$\begin{aligned} f_* &= \max_{w \in W} b^\top u, \\ W &= \{u \in R^m, v \in R^n : A^\top u + v = c, v \geq 0_n\}, \end{aligned} \quad (D')$$

which is equivalent to dual problem (D). The solution set of this problem is denoted by $W_* = [U_* \times V_*]$. For a given point $\hat{w}$ we find the least 2-norm projection $\hat{w}_*$ on W_* as a solution to the following minimization problem:

$$\begin{aligned} & \frac{1}{2} \|\hat{u}_* - \hat{u}\|^2 + \frac{1}{2} \|\hat{v}_* - \hat{v}\|^2 \\ &= \min_{w \in W_*} \left\{ \frac{1}{2} \|u - \hat{u}\|^2 + \frac{1}{2} \|v - \hat{v}\|^2 \right\}, \\ W_* &= \{u \in R^m, v \in R^n : A^\top u + v = c, v \geq 0_n, b^\top u = f_*\}. \end{aligned}$$

Using an approach similar to that used above we arrive at the following unconstrained maximization problem:

$$\begin{aligned} & \max_{y \in R^n} S^3(y, \gamma, \hat{w}), \text{ where } S^3(y, \gamma, \hat{w}) \\ &= -c^\top y + \hat{u}^\top A y \\ & \quad - \frac{1}{2} \|\gamma b - A y\|^2 - \frac{1}{2} \|(\hat{v} - y)_+\|^2. \end{aligned} \quad (15)$$

The following theorems hold.

Theorem 7. *There exists γ_* such that for all $\gamma \geq \gamma_*$ the unique least 2-norm projection $\hat{w}_*^\top = [\hat{u}_*^\top, \hat{v}_*^\top]$ of a point $\hat{w}^\top = [\hat{u}^\top, \hat{v}^\top]$ on W_* is given by*

$$\begin{aligned} \hat{u}_* &= \hat{u} + \gamma b - A y(\gamma), \\ \hat{v}_* &= (\hat{v} - y(\gamma))_+, \end{aligned}$$

where $y(\gamma)$ is a solution to the unconstrained maximization problem (15).

$1000 \times 10^5 \times 1$	LPP (MATLAB)	2660.8	8	2.1×10^{-7}	1.4×10^{-12}	7.1×10^{-7}

Theorem 8. For all $\gamma > 0$ and $\hat{w} = w_* \in W_*$ an exact solution to primal problem (P) is given by $x_* = y(\gamma)/\gamma$, where $y(\gamma)$ is a solution to the unconstrained problem (15).

To solve the primal and dual LP problems simultaneously, one can use the following iterative process similarly to the process (13,14):

$$y_{s+1} \in \arg \max_{y \in R^n} \left\{ -c^\top y + u_s^\top A y - \frac{1}{2} \|\gamma b - A y\|^2 - \frac{1}{2} \|(v_s - y)_+\|^2 \right\}, \quad (16)$$

$$u_{s+1} = u_s + \gamma b - A y_{s+1}, \quad (17)$$

$$v_{s+1} = (v_s - y_{s+1})_+. \quad (18)$$

Theorem 9. For all $\gamma > 0$ and for arbitrary starting point w_0 , the iterative process (16–18) converges to $w_* \in W_*$ in a finite number of iterations σ . The formula $x_* = y_{\sigma+1}/\gamma$ gives an exact solution to the primal problem (P).

The proofs of Theorems 7–9 are similar to the proofs of Theorems 1–3, respectively. The goal function $S^3(y, \gamma, \hat{w})$ of unconstrained maximization problem (15) is piecewise quadratic concave function. Therefore, one can define its generalized Hessian, which is $m \times m$ symmetric negative semidefinite matrix:

$$\frac{\partial^2}{\partial y^2} S^3(y, \gamma, \hat{w}) = -A^\top A - D(z).$$

Here, $D(z)$ denotes the $n \times n$ diagonal matrix with diagonal elements z^i , $i = 1, 2, \dots, n$. If $(\hat{v} - y)^i > 0$ then $z^i = 1$, if $(\hat{v} - y)^i \leq 0$ then $z^i = 0$. Now, for solving problem (15) one can use generalized Newton method.

There is an important difference between problems (10) and (15). In the first case, we look for the projection of a given point $\hat{u}$ on U_* , and in the second case we project a point $\hat{W} = [\hat{u}, \hat{v}]$ on the solution set W_* . Let $\hat{u}_*^1$ and $\hat{u}_*^2$ denote the projections of point $\hat{u}$ and $[\hat{u}, \hat{v}]$ in the first and second cases, respectively. Then the following inequality holds:

$$\|\hat{u}_*^1 - \hat{u}\| \leq \|\hat{u}_*^2 - \hat{u}\|.$$

The comparison of LP projection methods (which were implemented in MATLAB) with some well-known commercial and research software packages showed that they are competitive with the simplex and the interior point methods [1,5].

Table 1 presents the results of the test computations obtained using the program LPP, which implements method (11,12) in MATLAB, and other commercial and research packages [5]. Four randomly generated LP problems were solved on a 2.0 GHz Celeron computer with 1 Gb of memory. The following packages were used: BPMPD v. 2.3 (the interior point method) [6], MOSEK v.2.0 (the interior point method) [7], and the popular commercial package CPLEX (v.6.0.1, the interior point and simplex methods).

Table 1 shows the dimensions m and n of the problems, the density ρ of the nonzero

Figure 1. Computational time and speedup diagrams.

entries in the matrix A , the time T needed to solve the LP in seconds, and the number of iterations (for LP projection method (LPP), the total number of systems of linear equations that were solved in the Newton method when problem (11) was solved). Everywhere, parameter β was equal to 1, which exceeded β_* in these problems. Everywhere, $\hat{x} = 0_n$; that is, the normal solution (projection of the origin onto the primal solution set X_*) was sought in primal LP problem.

The l_∞ norms of the residual vectors were calculated:

$$\begin{aligned}\Delta_1 &= \|Ax - b\|_\infty \leq tol, \\ \Delta_2 &= \|(A^\top u - c)_+\|_\infty \leq tol, \\ \Delta_3 &= |c^\top x - b^\top u| \leq tol.\end{aligned}$$

It should be stressed that neither the linear program with 5 million variables, $\rho = 0.01$, $m = 1000$, nor those with 10^5 variables, $\rho = 1$, $m = 1000$, could be successfully solved by any of the codes listed above excepting the proposed LPP, which solved these problems in ≈ 16 and ≈ 44 min, respectively, and gave very high accuracy (less than 7.1×10^{-7}). Nevertheless, LPP code did not give the best results for small and moderate-size problems. As is evident from Table 1, BPMPD solver was superior to the others as applied for the first test problem; MOSEK solver showed the best results in the second test problem. Thus, the examples presented above have clearly demonstrated the principal effectiveness of the method proposed in solving the problems with a very large number ($\approx 10^6$) of nonnegative variables and a moderate ($\approx 10^3$) number of equality type constraints.

It is also evident that the results of LP projection algorithm are highly competitive to those of simplex and interior point methods, at the same time outperforming them in solving large LP problems.

Several parallel versions of the generalized Newton method for solving linear programs based on various data decomposition schemes of matrix A (column, row, and cellular schemes) were implemented [8]. The resulting parallel algorithms were successfully used to solve large-scale LP problems (up to several dozens of millions of variables

and several hundreds of thousands of constraints) for a relatively dense matrix A . The computational experiments were performed on the cluster consisting of two-processor nodes based on 1.6 GHz Intel Itanium 2 processors connected by Myrinet 2000. For example, for LP problem with 1 million variables and 10,000 constraints, the cellular scheme for 144 processors of the cluster accelerated the computations approximately by a factor of 50, and the computation time was 28 s. LP problem with 2 million variables and 200,000 constraints was solved in about 40 min on 80 processors. Another LP problem with 60 million variables and 4000 constraints was solved by column scheme in 140 s on 128 processors.

The computation time for typical test problems and the speedup for the different data decomposition schemes are shown in Fig. 1; where T_{tot} denotes the computation time in seconds, T_{lin} is the time spent on solving systems of linear equations, T_{rem} is the time spent on the other computations. Furthermore, S_{tot} denotes the parallel speedup in solving LP problem, S_{lin} is the parallel speedup in solving linear systems, and S_{rem} is the speedup of the other computations. Parameter β was equal to 100, which exceeded β_* in these problems. Everywhere, $\hat{x} = 0_n$; that is, the normal solution was sought in primal LP problem.

The development of an efficient solver was found to be a very challenging task; for every parallel variant of the algorithm, a reasonable trade-off between the computational scalability and the scalability in terms of memory had to be found. The highest speedup was obtained for the cellular scheme. However, depending on the dimension of the problem and the sparsity structure of the matrix A , the cellular, the row, or the column scheme was optimal.

PROBLEM STATEMENT

In various fields of human activity (engineering design, economic models, biology studies, etc.) different decision-making problems arise which can be often modeled by applying optimization concepts and tools. The decision-maker (engineer, physicist, chemist, economist, etc.) frequently wants to find the best combination of the set of parameters (geometrical sizes, electrical and strength characteristics, etc.) describing a particular optimization model which provides the optimum (minimum or maximum) of a suitable objective function, while it satisfies a certain collection of feasibility constraints. The objective function expresses overall system performance, such as profit, utility, risk, error, and so on. The constraints originate from physical, technical, economic, or some other considerations (see Refs 1–12, and the references therein).

The sophistication of the mathematical models describing the objects to be designed, which is the natural consequence of the growing complexity of these objects, significantly complicates the search for the best objective performance parameters. Many practical applications (see Refs 1–9, 11, 13–21, and the references therein) are characterized by optimization problems with several local solutions (typically, their number is unknown

and can be very high). These more complicated problems are usually referred to as *multiextremal* problems [8,10,11,17,22–25].

Nonlinear local optimization methods and theory (described in a vast literature, e.g., Refs 26–37, and the references therein) are not very successful for solving these multiextremal problems. As indicated, for example, in Refs 11 and 23, their limitation is due to the intrinsic multiextremality of the problem formulation and not due to the lack of smoothness or continuity—such properties are often present. It should be also mentioned in this context that in some problems a local solution may just be inappropriate. For example, if the objective function is an indicator of reliability and one is interested in assessing the worst case, then it is necessary to find the best (in this case, the worst) *global* solution [10,38].

Moreover, the objective function and constraints are often *black-box functions*. This means that there are “black-boxes” associated with each of these functions that, with the values of the parameters given in input, return the corresponding values of the functions and nothing is known to the optimizer about the way these values are obtained. Such functions are met in many engineering applications in which observation of the produced function values can be made, but analytical expressions of the functions are not available. For example, the values of the objective function and constraints can be obtained by running some computationally expensive numerical model, by performing a set of experiments, and so on. One may refer, for instance, to various decision-making problems in automatic control and robotics, structural optimization, safety verification problems, engineering design, network and transportation problems, mechanical design, chemistry and molecular biology, economics and finance or data classification (see Refs 1, 4–6, 8–12, 39–50, and the references therein).

To obtain estimates of the global solution related to a finite number of functions

evaluations, some suppositions on the structure of the objective function and constraints (such as continuity, differentiability, convexity, linearity, and so on) should be indicated. These assumptions play a crucial role in the construction of any efficient global search algorithm, able to outperform the simple uniform grid techniques in solving multiextremal problems. In fact, as observed for example in Refs 51–54, if no particular assumptions are made on the objective function and constraints, any finite number of function evaluations cannot guarantee getting close to the global minimum value, since this function may have very high and narrow peaks.

One of the natural and powerful (from both, the theoretical and the applied points of view) assumptions on the global optimization problem is that the objective function and constraints have bounded slopes. In other words, any limited change in the object parameters yields some limited changes in the characteristics of the objective performance. This assumption can be justified by the fact that in technical systems the energy of change is always limited (see the related discussion in Refs 11 and 55). One of the most popular mathematical formulations of this property is the Lipschitz continuity condition, which assumes that the difference (in the sense of a chosen norm) of any two function values is majorized by the difference of the corresponding function arguments, multiplied by a positive factor L . In this case, the function is said to be *Lipschitz* and the corresponding factor L is said to be the *Lipschitz constant*. The problem involving Lipschitz functions (the objective function and constraints) is said to be the *Lipschitz global optimization problem*.

Formally, a general Lipschitz global optimization problem can be stated as follows:

$$f^* = f(x^*) = \min f(x), \quad x \in \Omega \subset \mathbb{R}^N, \quad (1)$$

where Ω is a bounded set defined by the following formulae

$$\Omega = \{x \in D : g_i(x) \leq 0, 1 \leq i \leq m\}, \quad (2)$$

$$D = [a, b] = \left\{x \in \mathbb{R}^N : a(j) \leq x(j) \leq b(j), \right. \\ \left. 1 \leq j \leq N \right\}, \quad a, b \in \mathbb{R}^N, \quad (3)$$

with N being the problem dimension. In Equations (1)–(3), the objective function $f(x)$ and the constraints $g_i(x)$, $1 \leq i \leq m$, are multiextremal, non necessarily differentiable, black-box (and, thus, hard to evaluate) functions that satisfy the Lipschitz condition over the search hyperinterval D :

$$|f(x') - f(x'')| \leq L \|x' - x''\|, \quad x', x'' \in D, \quad (4)$$

$$|g_i(x') - g_i(x'')| \leq L_i \|x' - x''\|, \quad x', x'' \in D, \\ 1 \leq i \leq m, \quad (5)$$

where $\|\cdot\|$ denotes, usually, the Euclidean norm, L and L_i , $1 \leq i \leq m$, are the (unknown) Lipschitz constants such that $0 < L, L_i < \infty$, $1 \leq i \leq m$.

Note also that, due to the multiextremal character of the constraints, the admissible region Ω can consist of disjoint, non-convex subregions. More generally, not all the constraints (and, consequently, the objective function too) are defined over the whole region D : namely, a constraint $g_{i+1}(x)$ (or the objective function $f(x)$) can be defined only over subregions where $g_i(x) \leq 0$, $1 \leq i \leq m$. In this case, the problems (1)–(5) are said to be *with partially defined constraints*. If $m = 0$ in Equation (2), the problem is said to be *box-constrained*.

Such problems are encountered very frequently in practice. Let us refer only to the following examples: general (Lipschitz) nonlinear approximation; solution of nonlinear equations and inequalities; calibration of complex nonlinear system models; black-box systems optimization; optimization of complex hierarchical systems (related, for example, to facility location, mass-service systems), and so on (see Refs 8–11, 17, 25, 56, 57, and the references given therein). Thus, numerous algorithms have been proposed (see, e.g., Refs 8, 11, 12, 17, 23, 52, 55, 56, 58–75, and the references therein) for solving the problems (1)–(5).

Sometimes, the problems (1), (3), and (4) with a differentiable objective function having the Lipschitz (with an unknown Lipschitz

constant) first derivative $f'(x)$ (which could itself be a costly multiextremal black-box function) is included in the same class of Lipschitz global optimization problems (theory and methods for solving this differentiable problem can be found in Refs 8, 10, 11, 70, 76–86).

It should be stressed that not only multidimensional global optimization problems but also one-dimensional ones (in contrast to one-dimensional local optimization problems that have been very well studied in the past) continue to attract attention of many researchers. These happens at least for two reasons. First, there exists a large number of applications where it is necessary to solve such problems [10,11,87–93]. Second, there exist numerous approaches [8,10–12,17,23,55,81,94–96] that enable to generalize to the multidimensional case the methods propose for solving univariate problems.

It is also noteworthy that it is not easy to find suitable ways for managing multiextremal constraints (Eq. 2). For example, the traditional penalty approach (see Refs 17, 23, 26, 36, 97, and the references therein) requires that $f(x)$ and $g_i(x)$, $1 \leq i \leq m$, are defined over the whole search domain D . At first glance it seems that at the regions where a constraint is violated the objective function can be simply filled in with either a big number or the function value at the nearest feasible point [17,23,98]. Unfortunately, in the context of Lipschitz algorithms, incorporating such ideas can lead to extremely high Lipschitz constants, causing degeneration of the methods and nonapplicability of the penalty approach (see the related discussion in Refs 8, 10, 11, 25, 56).

A promising approach called the *index scheme* has been proposed in Refs 99 and 100 (see also Refs 11, 101, 102) to reduce the general constrained problems (1)–(5) to a box-constrained discontinuous problem. An important advantage of the index scheme is that it does not introduce additional variables and/or parameters by opposition to widely-used traditional approaches. It has been recently shown in Ref. 103 that the index scheme can be also successfully used in combination with the

branch-and-bound approach [8,10,23,104] if the Lipschitz constants from Equations (4)–(5) are known *a priori*. An extension of the index approach, originally proposed for information-stochastic Bayesian algorithms, to the framework of geometric algorithms, constructing nondifferentiable discontinuous minorants for the reduced problem, has been also examined [92,105–107].

Therefore, in order to expose the principal ideas of some known approaches to solving the stated problem, the box-constrained Lipschitz global optimization problem (Eqs 1, 3, and 4) will be considered in the next two sections. In particular, these approaches will be distinguished by the mode in which information about the Lipschitz constants is obtained and by the strategy of exploration of the search hyperinterval D from Equation (3).

USAGE OF THE LIPSCHITZ CONDITION

The Lipschitz continuity assumption, being quite realistic for many practical problems (see Refs 8–11, 17, 23, 25, and the references given therein), is also an effective tool for constructing global optimum estimates with a finite number of function evaluations, which allows one to construct global optimization algorithms and to prove their convergence and stability.

In fact, the Lipschitz condition allows us to give its simple geometric interpretation (Fig. 1). Once a one-dimensional Lipschitz (with the Lipschitz constant L) function $f(x)$ has been evaluated at two points x' and x'' , due to Equation (4), the following four inequalities take place over the interval $[x', x'']$

$$\begin{aligned} f(x) &\leq f(x') + L(x - x'), \\ f(x) &\geq f(x') - L(x - x'), x \geq x', \\ f(x) &\leq f(x'') - L(x - x''), \\ f(x) &\geq f(x'') + L(x - x''), x \leq x''. \end{aligned}$$

Thus, the function graph over the interval $[x', x'']$ must lie inside the area limited by four lines which pass through the points $(x', f(x'))$ and $(x'', f(x''))$ with the slopes $\pm L$ (see the light grey parallelogram in Fig. 1).

Figure 1. Graphical interpretation of the Lipschitz condition.

If the function $f(x)$ is to be minimized over the interval $[x', x'']$, its lower bound over this interval can be easily calculated. In fact, due to the Lipschitz condition (4), the following inequality is satisfied

$$f(x) \geq F(x),$$

where $F(x)$ is a piecewise linear function over $[x', x'']$

$$F(x) = \max\{f(x') - L(x - x'), f(x'') + L(x - x'')\}, \\ x \in [x', x''].$$

The minimal value of $F(x)$ over $[x', x'']$ is therefore the lower bound of $f(x)$ over this interval. It is calculated as

$$R = R_{[x', x'']} = F(\hat{x}) = \frac{f(x') + f(x'')}{2} - L \frac{x'' - x'}{2} \quad (6)$$

and is obtained at the point

$$\hat{x} = \frac{x' + x''}{2} - \frac{f(x'') - f(x')}{2L} \quad (7)$$

(Fig. 1).

The described geometric interpretation lies in the basis of the Piyavskij–Shubert method (see Refs 68 and 71)—one of the first and well studied algorithms for the one-dimensional Lipschitz global optimization, discussed in a vast literature; e.g., the survey [52] and the references given therein; various modifications of this algorithm have been also proposed in Refs 23, 52, 58, 60, 108–110). As observed, for example in Refs

111–114, this algorithm is “optimal in one step,” that is, the choice of the current evaluation point as in Equation (7) ensures maximum increase of the lower bound of the global minimum value of $f(x)$ with respect to a number of reasonable criteria (see Refs 11, 23, 25, 115 for the related discussions on optimality principles in Lipschitz global optimization).

The Piyavskij–Shubert method belongs to the class of *geometric algorithms*; that is, algorithms that use in their work auxiliary functions to estimate behavior of $f(x)$ over the search region, as just described. This idea has proved to be very fruitful and many algorithms (both one-dimensional and multi-dimensional ones; see Refs 52, 58, 61, 67, 74, 76, 110, 116–118, and the references given therein) based on constructing, updating, and improving auxiliary piecewise minorant functions built using an overestimate of the Lipschitz constant L have been proposed. Close geometric ideas have been used for other classes of optimization problems, as well. For example, various aspects of the so-called α BB-algorithm for solving constrained nonconvex optimization problems with twice-differentiable functions have been examined in Refs 45, 119, 120 (see also Refs 15 and 121). The α BB-algorithm combines a convex lower bounding procedure (based on a parameter α that can be interpreted in a way similar to the Lipschitz constant) within the branch-and-bound framework, whereas nonconvex terms are underestimated through quadratic functions derived from second-order information.

As shown, in Refs 10, 11, 122, there exists a strong relationship between the geometric approach and another possible technique of solving the stated problem—the so-called *information-statistical approach*. This approach originated in Refs 72 and 123 (see also Refs 11 and 55) and, together with Piyavskij–Shubert method, it has consolidated foundations of the Lipschitz global optimization. The main idea of this approach is to apply the theory of random functions to building a mathematical representation of available (certain or uncertain) *a priori* information on the objective function behavior. A systematic approach to the description of some uncertain information on this behavior is to accept that the unknown black-box function to be minimized is a sample of some known random function. Generally, to provide an efficient analytical technique for deriving some estimates of global optimum with a finite number of trials, that is for obtaining by Bayesian reasoning some conditional (with respect to the trials performed) estimations, the random function should have some special structure. Thus, it is possible to deduce the decision rules for performing new trials as some optimal decision functions [11,12,25,42,55,75,124–131].

One of the main questions to be considered in solving the Lipschitz global optimization problem is, how can the Lipschitz constants L and L_i , $1 \leq i \leq m$ be specified? For clarity, let us speak only about the Lipschitz constant L of the objective function $f(x)$ from Equation (1). There are several approaches to specify the Lipschitz constant. For example, it can be given *a priori* [17,23,52,58,66–68,71,74,132,133]. This case is very important from the theoretical viewpoint but is not easily obtained in practice. More practical approaches are based on an adaptive estimation of L in the course of the search. In such a way, algorithms can use either a *global* estimate of the Lipschitz constant [8,11,23,55,65,72,134] valid for the whole region D from Equation (3), or *local* estimates L_i valid only for some subregions $D_i \subseteq D$ [10,11,69,122,135,136]. Estimating local Lipschitz constants during the work of a global optimization algorithm allows

one to significantly accelerate the global search (the importance of the estimation of local Lipschitz constants has also been highlighted in other works; [8,76,137]). Naturally, balancing between local and global information must be performed in an appropriate way [10,11,69] to avoid missing the global solution. Finally, estimates of L can be chosen during the search from a certain set of admissible values from zero to infinity [10,64,98,138–141]. It should be stressed that either the Lipschitz constant is known and an algorithm is constructed correspondingly, or it is not known but there exist sufficiently large values of parameters of the considered algorithm, ensuring its convergence.

Note that the Lipschitz constant has also a significant influence on the convergence speed of numerical algorithms and, therefore, the problem of its specifying is of the great importance for the Lipschitz global optimization [8,10,11,25,52,57,64,69,136,137,142]. An underestimate of the Lipschitz constant L can lead to the loss of the global solution. In contrast, accepting a very high value of L for a concrete objective function means (due to the Lipschitz condition (4)) assuming that the function has a complicated structure with sharp peaks and narrow attraction regions of minimizers within the whole admissible region. Thus, an overestimate of L (if it does not correspond to the real behavior of the objective function) leads to a slow convergence of the algorithm to the global minimizer.

MULTIDIMENSIONAL APPROACHES

Since the uniform grid techniques require a substantial number of evaluation points, they can be successfully applied only if the dimensionality N from Equation (3) is small or the required accuracy is not high. As observed in Refs 8, 11, 17, 143, an adaptive selection of evaluation points $x^1, x^2, \dots, x^k$ usually outperforms the grid technique. Such a selection aims to ensure a higher density of the evaluation points near the global minimizer x^* with respect to the densities in the rest of the search domain D .

Figure 2. An example of a two-dimensional lower bounding function for an objective function $f(x)$, $x = (x_1, x_2) \in D \subset \mathbb{R}^2$.

One of these adaptive approaches is a direct extension of the one-dimensional geometric algorithms to the multidimensional case. At each iteration $k \geq 1$ of such an algorithm, a function

$$F_k(x) = \max_{1 \leq i \leq k} \{f(x^i) - \hat{L} \|x - x^i\|\}, \quad \hat{L} > L, \quad x \in D, \quad (8)$$

is constructed which is a lower bounding function (minorant) for $f(x)$ (due to the Lipschitz condition (4)), that is,

$$f(x) \geq F_k(x), \quad \forall k \geq 1, \quad x \in D.$$

A global minimizer of the function (8) is determined and chosen as a new evaluation point for $f(x)$, that is,

$$x^{k+1} = \arg \min_{x \in D} F_k(x). \quad (9)$$

A new minorant function (8) is constructed and the process is repeated, until a stopping criterion is satisfied. For example, the algorithm can be stopped when the difference between the current estimate of the minimal function value and the global minimum of $F_k(x)$, which is a lower bound on the global minimum of $f(x)$, becomes smaller than some prescribed value.

Geometrically, the graph of $F_k(x)$ in $\mathbb{R}^{N+1}$ is defined by a set of k intersecting N -dimensional cones bounded by the hyper-interval $D \subset \mathbb{R}^N$, with vertices $(x^i, f(x^i))$,

$1 \leq i \leq k$, and the slope $\hat{L}$. Axes of symmetry of these cones are parallel to the $(N+1)$ -th unit vector and their sections orthogonal to the axes are spheres (Fig. 2).

In the case of one dimension ($N = 1$), there are no serious problems in calculating x^{k+1} from Equation (9). In fact, this is reduced to selecting the minimal value among k values, each of which is easy to compute due to the explicit formula (6). If $N > 1$, then the relations between the location of the next evaluation point and the results of the already performed evaluations become significantly more complicated. Therefore, finding the point x^{k+1} is usually the most time-consuming operation of the multidimensional algorithm, and its complexity increases with the growth of the problem dimension.

In Refs 52 and 68, it is observed that the global minimizer x^{k+1} of the minorant function $F_k(x)$ belongs to a finite set of points; that is, local minima of $F_k(x)$, which can be computed by solving systems of quadratic equations. In Ref. 67, a deep analysis of the algorithm constructing lower bounding functions $F_k(x)$ from Equation (8) is presented and a more efficient way to find their local minima is proposed, which requires solving systems of N linear and one quadratic equations. Algebraic methods aiming to avoid computing solutions of some systems which do not correspond to global minima of $F_k(x)$ are considered in Ref. 144. In Ref. 52,

it is indicated that the number of systems to be examined can be further reduced.

In Refs 74 and 145, cones with spherical base (Eq. 8) are replaced by cones with simplex base. At each iteration, there exists a collection of such inner approximating simplices in $\mathbb{R}^{N+1}$ that bound parts of the graph of the objective function $f(x)$ from below, always including the part containing the global minimum point (x^*, f^*) from Equation (1). Various aspects of generalization of this technique are discussed in Refs 76 and 118.

In Ref. 146, minorant functions similar to Equation (8) are considered. The solution of Equation (9) still remains difficult, the problem of the growth of complexity of Equation (9) is analyzed, and a strategy for dropping elements from the sequence of evaluation points while constructing a minorant function is proposed.

Unfortunately, the difficulty of determining a new evaluation point (Eq. 9) in high dimensions (after executing even relatively small number of function evaluations) has not been yet overcome. It should be noted here that, as observed in Ref. 11, this difficulty is usual for many approaches aiming to decrease the total number of evaluations by adaptively constructing an auxiliary function approximating $f(x)$ over the search domain D . They introduce some selection rule of the type (9) and the auxiliary function $F_k(x)$ used in such a rule often happens to be essentially multiextremal (though its construction may be connected with assumptions quite different from the Lipschitz condition (4)). Moreover, in this case, it is difficult to use adaptive estimates of the global or local Lipschitz constant(s). This can pose a further limitation for the practical application of the considered methods directly extended the one-dimensional Piyavskij–Shubert algorithm to the multidimensional case.

In order to simplify the task of calculating lower bounds of $f(x)$ and determining new evaluation points, many multidimensional methods subdivide the search domain $D = [a, b]$ from Equation (3) into a set of subdomains D_i , obtaining at each iteration k a

partition $\{D^k\}$ of D such that

$$D = \bigcup_{i=1}^M D_i, \quad D_i \cap D_j = \delta(D_i) \cap \delta(D_j), \quad i \neq j, \quad (10)$$

where $M = M(k)$ is the number of subdomains D_i during the k th iteration and $\delta(D_i)$ denotes the boundary of D_i . An approximation of $f(x)$ over each subregion D_i from $\{D^k\}$ is based on the results obtained by evaluating $f(x)$ at some points $x \in D$.

If a partition of D into hyperintervals D_i is used in Equation (10) and the objective function is evaluated, for example, at the central point of every hyperinterval D_i (the so-called *center-sampling partition strategies*—see for example, Refs 61, 64, 66, 98, 137, 139, 147), each cone from Equation (8) can be considered over the corresponding hyperinterval D_i , independently of the other cones. This allows one to avoid the necessity of establishing the intersections of the cones and to simplify the lower bound estimation of $f(x)$ when a new evaluation point is determined by a rule such as Equation (9). The more accurate estimation of the objective function behavior can be achieved when two evaluation points over a hyperinterval are used for constructing an auxiliary function for $f(x)$, for example, at the vertices corresponding to the main diagonal of hyperintervals (the so-called *diagonal partition strategies* [8,10,23,65,83,86,122,141,148]).

In exploring the multidimensional search domain D , various multisection techniques for partitions of hyperintervals have been also studied in the framework of interval analysis [149–154]. More complex partitions based on simplices [22,23,155–158] and auxiliary functions of various nature have also been introduced [76,78,145,159–165]. Several attempts to generalize various partition schemes in a unique theoretical framework have been made [8,23,63,104,166–168].

Another fruitful approach to solving multidimensional Lipschitz global optimization problems consists of extending some efficient one-dimensional algorithms to the multidimensional case. There exist at least three extensions of these algorithms to the multidimensional case: *nested global optimization*

scheme [68,169], *reduction of the dimension by using Peano curves* [11,55], and *diagonal approach* [8,10], which is a special case of the scheme of adaptive partition algorithms (or a more general scheme of the “*divide the best*” algorithms [10,104]).

In the nested optimization scheme [68,169] (see also Refs 11, 22, 55, 95), the minimization over D of the Lipschitz function $f(x)$ from (1) is made using the following nested form

$$\min_{x \in D} f(x) = \min_{a(1) \leq x(1) \leq b(1)} \dots \min_{a(N) \leq x(N) \leq b(N)} f(x(1), \dots, x(N)).$$

This allows one to solve the multidimensional problem (1),(3),(4) by solving a set of univariate problems and, thus, to apply the methods proposed for the one-dimensional optimization.

The second dimensionality reduction approach [11,38,55,171,172] is based on the application of a single-valued Peano-type curve $x(\tau)$ continuously mapping the unit interval $[0, 1]$, $\tau \in [0, 1]$, onto the hyperinterval D . These curves, introduced by Peano and further by Hilbert, pass through any

point of D ; that is, “fill” the hypercube D , and this gave rise to the term *space-filling curves* [173,174] or just *Peano curves*. Particular schemes for the construction of various approximations to Peano curves, their theoretical justification, and the standard routines implementing these algorithms are given [11,55,143,175].

If $x(\tau)$ is Peano curve, then from the continuity (due to Equation (4)) of $f(x)$ it follows that

$$\min_{x \in D} f(x) = \min_{\tau \in [0, 1]} f(x(\tau)), \quad (11)$$

and this reduces the original multidimensional problem (Eqs 1,3,4) to one dimension (Fig. 3). Moreover, it can be proved [11] that if the multidimensional function $f(x)$ from Equation (1) is Lipschitz with a constant L , then the one-dimensional function $f(x(\tau))$, $\tau \in [0, 1]$, satisfies the uniform Hölder condition over $[0, 1]$ with the exponent N^{-1} and the coefficient $2L\sqrt{N+3}$

$$|f(x(\tau')) - f(x(\tau''))| \leq 2L\sqrt{N+3}(|\tau' - \tau''|)^{1/N}, \quad \tau', \tau'' \in [0, 1]. \quad (12)$$

Figure 3. Usage of an approximation of the Peano curve for global optimization: A two-dimensional function from the class [170] has been evaluated at six points belonging to the curve.

Thus, the Lipschitz assumption does not hold for the function $f(x(\tau))$ at the right-hand side of Equation (11), which satisfy the more general Hölder condition (12). However, as shown, [11,55,176–179], many Lipschitz one-dimensional algorithms can be generalized to the case of minimization of Hölder functions too. In the monograph [11], many powerful sequential and parallel global optimization methods based on the usage of Peano curves are proposed and analyzed in depth.

Finally, in the diagonal approach [8,10,148,180] to solving Lipschitz global optimization problems, the initial hyperinterval D from Equation (3) is partitioned into a set of smaller hyperintervals D_i , the objective function is evaluated only at two vertices corresponding to the main diagonal of hyperintervals of the current partition of D , and the results of these evaluations are used to select a hyperinterval for the further subdivision. The diagonal approach has a number of attractive theoretical properties and has proved to be efficient in solving applied problems (see Refs 8, 10, 141, and the references therein).

The extension of one-dimensional global optimization algorithms to the multidimensional case can be performed naturally by means of the diagonal scheme [8,10,65,135,141,148,180,181]. In order to decrease the computational efforts needed to describe the objective function $f(x)$ at every small hyperinterval $D_i \subset D$, $f(x)$ is evaluated only at the vertices a_i and b_i corresponding to the main diagonal of D_i . At every iteration the “merit” of each hyperinterval so far generated is estimated. The higher “merit” of a hyperinterval D_i corresponds to the higher possibility that the global minimizer x^* of $f(x)$ belongs to D_i . The “merit” is measured by a real-valued function R_i called a *characteristic* [10,11,22]. In order to calculate the characteristic R_i of a multidimensional hyperinterval D_i , some one-dimensional characteristics can be used as prototypes. After an appropriate transformation they can be applied to the one-dimensional segment being the main diagonal $[a_i, b_i]$ of the hyperinterval D_i . A hyperinterval having the “best” characteristic (e.g., the biggest one, as in the information approach [11,55,174];

or the smallest one, as in the geometric approach, [10,11,136]) is partitioned by means of a partition operator (*diagonal partition strategy*), and new evaluations are performed at two vertices corresponding to the main diagonal of each generated hyperinterval. The concrete choice of the characteristic R_i and the partition strategy determines the particular diagonal method [8,10,23,64,122,135,139,141,148], and the references therein).

Different exploration techniques based on various diagonal adaptive partition strategies have been analyzed in Ref. 10 (see also Ref. 8). It has been demonstrated in Refs 10 and 148 that partition strategies traditionally used in the framework of the diagonal approach may not fulfill the requirements of computational efficiency because of the execution of many redundant evaluations of the objective function. Such a redundancy slows down significantly the global search in the case of costly functions.

A new diagonal adaptive partition strategy, originally proposed in Ref. 148 (see also Refs 10 and 147), that allows one to avoid this computational redundancy has been thoroughly described in Ref. 10. It can be also viewed as a procedure generating a series of curves similar to Peano space-filling curves—the so-called *adaptive diagonal curves*. However, the order of partition of the adaptive diagonal curves is different within different subdomains of the search domain. A particular diagonal algorithm developed by using the new partition strategy constructs its own series of curves, taking into account properties of the problem to be solved. The curves become denser in the vicinity of the global minimizers of the objective function if the selection of hyperintervals for partitioning is realized appropriately (Fig. (4)). Thus, these curves can be used for reducing the problem dimensionality similarly to Peano curves but in a more efficient way.

In Ref. 10, it is demonstrated theoretically and numerically that the new strategy considerably speeds up the search and also leads to saving computer memory. It is particularly important that its advantages become more pronounced when the problem dimension N increases. Thus, fast one-dimensional

Figure 4. Usage of adaptive diagonal curves (evaluation points from 1 to 12), generated by the efficient diagonal partition strategy, for minimizing a multiextremal two-dimensional objective function from the class [182].

methods can be efficiently extended to the multidimensional case by using this scheme. Moreover, the proposed partition strategy can be subsequently parallelized by for example, the technique from Refs 11 and 183 (where theoretical results regarding non-redundant parallelism have been obtained, as well), allowing one to speed up further.

Finally, it should be emphasized that particular attention should be also paid to the problem of testing global optimization algorithms. The lack of such information as number of local optima, their locations, attraction regions, local and global values, describing global optimization tests taken from real-life applications, creates additional difficulties in verifying validity of the algorithms. Some benchmark classes and related discussions can be found in Refs 4, 10, 11, 17, 25, 59, 170, 184–191.

LITTLE'S LAW AND RELATED RESULTS

RONALD W. WOLFF

Department of Industrial Engineering and
Operations Research, University of
California at Berkeley, Berkeley,
California

Queueing theory is about the analysis of mathematical models where entities called *customers* arrive at some facility called the *system*, spend *waiting time* in system, and then depart.

In its early history, methods of analysis were tailored to individual models and varied widely. There were no theorems of any consequence that held across the board from model to model. This changed in 1961 with " $L = \lambda W$ " [1] by John Little, often called *Little's Law* today, and we will sometimes abbreviate as "LL." It, together with extensions, is of fundamental importance for both the foundations of queueing theory and its applications. The literature on this topic since then is enormous. It is impossible to review all of that here. Instead, our goal is to explain LL and important extensions, demonstrate their usefulness, show the connection with some related topics, and provide a literature guide sufficient for further investigation.

LL states that the time average of the number of customers in system is the product of the arrival rate and the customer average of the waiting times.

This article is organized as follows. We present an intuitive explanation and illustrate applications of LL in the section titled "Notation, Explanation, Applications." There are two versions of LL. We prove the sample-path version in the section titled "Sample-Path Proof of Little's Law," treat the stationary version in the section titled "Stationary Version of Little's Law," and extend LL in the section titled "Extension to $H = \lambda G$; Work." We present the equivalence of $H = \lambda G$ to a result in the section titled "A Rate Conservation Law," present another related result in the section titled "A Distributional Little's

Law," and review the literature and other related results in the section titled "Brief History and Literature Review."

NOTATION, EXPLANATION, APPLICATIONS

For $i \geq 1$, let customer C_i arrive at time t_i , have waiting W_i , and depart at $t_i + W_i$, where $t_0 \equiv 0 \leq t_1 \leq t_2 \leq \dots$. For any $t \geq 0$, C_i is *in the system* at t if $t_i \leq t < t_i + W_i$. Define the corresponding indicator, $I_i(t) = 1$ if $t_i \leq t < t_i + W_i$, and $I_i(t) = 0$ otherwise, where $\int_0^\infty I_i(t) dt = W_i$. Let $N(t) = \sum_{i=1}^\infty I_i(t)$, the *number of customers in system* at time t , and $\Lambda(t) = \max\{i : t_i \leq t\}$, the number of arrivals by time t . With $\Lambda(t)$, we rewrite $N(t) = \sum_{i=1}^{\Lambda(t)} I_i(t)$.

From customer data $\{t_i\}$ and $\{W_i\}$ for all i , we can construct $\{N(t)\}$ for all t . We plot $\{\Lambda(t)\}$ as a step function and show some customer waiting-time data in Fig. 1, and the constructed $\{N(t)\}$ in Fig. 2.

In Fig. 1, C_3 arrives after but departs before C_2 . There is no way to deduce this from Figure 2, which tells us only how many customers are in the system, not *which* customers are there. It has less information than Fig. 1.

While waiting times are lengths of time, they are also displayed as rectangles of height 1 in Fig. 2. Thus *length* W_i is also *area* W_i . For each t , $N(t)$ is simply the number of waiting time rectangles that contain point t .

In a (stochastic) queueing model, t_i , W_i , and $N(t)$ are random variables; $\{t_i, i \geq 1\}$, $\{W_i, i \geq 1\}$, and $\{N(t), t \geq 0\}$ are stochastic processes. These random quantities are defined on some sample space. At ω , some arbitrary point in this space, $t_i(\omega)$, $W_i(\omega)$, and $N(t, \omega)$ are numbers, and the collection of stochastic processes is called a *sample path* or *realization*. A simulation of a queueing model generates a sample path. We may also observe a real system as it evolves over time without having a formal model, and view the observed evolution of arrivals, waiting times, and number in system as a sample path.

Usually, assumptions are made such that *stationary versions* of these processes exist, where in particular for these versions, W_i has the same distribution for all i and $N(t)$ has the same distribution for all t . Let W and N be corresponding random variables that have these distributions.

There are two versions of Little's Law. The *sample-path* version relates sample-path averages at some ω in the sample space; the *stationary* version relates the expected values of W and N . The former is easy to understand and so intuitively appealing that, to some, it may not require a proof (we think it does). It also applies to data collected on real systems. The latter is a common way to find these quantities, and is an important tool for the analysis of queueing models. We now present the sample-path version, but omit writing ω explicitly; for example, we write W_i rather than $W_i(\omega)$.

Rectangular area W_i is the contribution to the area under $\{N(t)\}$ that is made by customer C_i . Now consider the area under $\{N(t)\}$ on some interval $(0, T)$, where, as in Figs 1 and 2, T has the property that $N(T) = 0$. For any such T , this area may be

written either as an integral or a sum,

$$\int_0^T N(t) dt = \int_0^T \sum_{i=1}^{\Lambda(t)} I_i(t) dt = \sum \int = \sum_{i=1}^{\Lambda(T)} W_i,$$

where in our figures, $\Lambda(T) = 4$. For any T where $N(T) > 0$, Equation (1) does not hold because a portion of at least one rectangle in the sum contributes to the area under $\{N(t)\}$ after T . In this case, sum – integral $\equiv$ error ≥ 0 . We define long run averages as limits, when they exist, and name them.

$$L = \lim_{T \rightarrow \infty} \frac{1}{T} \int_0^T N(t) dt, \quad w = \lim_{n \rightarrow \infty} \frac{1}{n} \sum_{i=1}^n W_i, \\ \lambda = \lim_{t \rightarrow \infty} \frac{\Lambda(t)}{t}, \quad (1)$$

where L is the average number of customers in the system, w is the average waiting time (of customers in the system), and λ is the arrival rate.

L and w are the two most common performance measures for a queue. We present an intuitive explanation below and a proof in the section titled “Sample-Path Proof of Little's

Figure 1. Waiting time data.

Figure 2. Number of customers in system data.

Law” of this fundamental relation between them (sample-path version):

Theorem 1 [Little’s Law, LL, or $L = \lambda w$]. *If limits λ and w exist and are finite, L exists and is finite, where*

$$L = \lambda w. \quad (2)$$

The basic reason for Equation (3) is Equation (1). For any T (where now $N(T) \geq 0$) we write

$$\begin{aligned} \frac{\int_0^T N(t) dt}{T} &= \frac{\sum_{i=1}^{\Lambda(T)} W_i}{T} - \frac{\text{error}}{T} \\ &= \left(\frac{\Lambda(T)}{T} \right) \left(\frac{\sum_{i=1}^{\Lambda(T)} W_i}{\Lambda(T)} \right) - \frac{\text{error}}{T}. \end{aligned}$$

As T gets large, the first quantity in parenthesis on the right approaches λ , the second approaches w , and the product approaches λw . Hence Theorem 1 holds if the term on the far right approaches 0 as $T \rightarrow \infty$. The error term itself need not get small, but only grows more slowly than T .

Note that Equation (3) holds for some unspecified ω . If limits w and λ hold as constants on a set of ω with probability 1 (w.p.1), Equation (3) holds as a constant w.p.1.

Usually, “ $L = \lambda w$ ” is written “ $L = \lambda W$.” We prefer to use W and N as defined above, in order to write the stationary version as $E(N) = \lambda E(W)$; see the section titled “Stationary version of Little’s Law.” The notation “ L ” has a long history, meaning the average length of a waiting *line*. We now present an application, based on personal experience.

Example 1 [Wine Cellars]. There are about 3000 bottles in my friend Loy’s wine cellar ($L = 3000$). He does not keep records of when each bottle was bought and consumed. He wondered “about how old, on average, are these wines when they are drunk?” He estimates that (with some help) he consumes about 300 bottles per year ($\lambda = 300$). The

answer to his question is $w = L/\lambda = 10$ years. Not quite true. They are on average 10 years older than when he bought them.

When designing my wine cellar, I had to decide its size. I estimated that on average, wines would be held 5 years when they are drunk ($w = 5$ years), and I would drink about 200 bottles per year ($\lambda = 200$). Thus $L = \lambda w = 1000$ bottles, and the capacity of the wine cellar should be somewhat larger to account for fluctuations about the average. (Fluctuations are much less in wine cellars than in a typical queueing model.) It turned out that the wine cellar was too small. What went wrong? Not LL. I had underestimated λ !

Viewing the system as a “black box,” we do not have to know anything about what goes on inside the box; LL holds. In this example, it is natural to think of a collection of wine bottles as *inventory*, and in fact, queueing theory is closely related to what is called *inventory theory*. These theories differ in how we model what goes on inside the box, what aspects of the model may be subject to some control, and what decisions are being contemplated.

In most queueing models, the arrival process is treated as given. At a wine shop, arrivals are scheduled. At a wine cellar, both arrivals and departures are scheduled. We now describe some queueing models of what is inside the box.

In elementary situations, each arrival at a facility has a *service time* to be performed by a server, where the facility has one or more servers. Arrivals, finding all servers busy serving other customers, wait in a queue. While in the system, a customer may spend some time in queue, followed by a service time.

The time that a customer spends in queue before service begins we call *delay in queue* or just *delay* (sometimes called *waiting time in queue*). Thus a customer’s waiting time is the *sum* of the corresponding delay and service time.

Similarly, at any time there will be a *queue length* (number of customers in queue) and a *number of customers in service*, where their sum is the *waiting-line length* (number of customers in system).

Figure 3. Snapshot of a queueing system.

In Fig. 3, we show a “snapshot” of a system where customers are represented as circles and servers as square boxes. We have five customers in queue, two servers, two customers in service, and a total of seven customers in system.

Let C_i have delay D_i and service time S_i , $i \geq 1$, where $W_i = D_i + S_i$. Similarly, let $N_q(t)$ and $N_s(t)$ be the respective (constructed) number of customers in queue and in service at time t , $t \geq 0$, where $N(t) = N_q(t) + N_s(t)$.

Let the customer average of $\{D_i\}$ and $\{S_i\}$ be d and $E(S)$, respectively, where the notation “ $E(S)$ ” is often used because, in many applications, the service times S_i are independent and identically distributed (i.i.d.) random variables, and their customer average is their expected value. Let the time average of $\{N_q(t)\}$ and $\{N_s(t)\}$ be, respectively, Q and L_s . From LL, we immediately have

$$Q = \lambda d \text{ and } L_s = \lambda E(S). \quad (3)$$

To obtain Equation (4), we did not mention the order of service of customers in queue. In Fig. 3, it would appear to be first-in-first-out (FIFO), also called *first-come-first-served* (FCFS); FIFO is easier to pronounce. Some alternatives are last-in-first-out (LIFO) and shortest job (service time) first (SJF). SJF usually (but not necessarily) reduces both Q and d . Equation (4) holds in each case. We do not have to know what is going on inside the customers-in-queue box.

Is λ in the expression for Q in Equation (4) correct? Arrivals finding an idle server do not join the queue. To investigate, let β be the (long run) fraction of arrivals who find all servers busy and join the queue, so $\beta\lambda$ is the arrival rate of these customers. Let d_β be the average delay of these customers. From LL, $Q = \beta\lambda d_\beta$. The average delay of customers

who do not join the queue is 0, and averaging over both groups, $d = \beta d_\beta + (1 - \beta)0 = \beta d_\beta$, and indeed, $Q = \lambda d$ is correct. For LL, L , λ , and w must be averages over the same stream of customers.

The second equation in Equation (4) also deserves a closer look. It is the average number of customers in service, assuming all are served. This will be true when the number of servers exceeds $\lambda E(S)$, which is also the average number of busy servers. When there is one server, it is the fraction of time that server is busy.

Little’s Law may be applied in several ways. If either L or w is known or can be found by an independent analysis (and we know λ), then we know the other. In other applications, this equation, together with other information, determines both quantities. In a typical queueing *model*, λ is known (is a parameter). In a real system, it is not known; sometimes it is estimated from estimates of L and w . We now illustrate a different application.

Example 2 [Order of Service]. At one time at banks and post offices in the United States, a separate queue formed at each teller (server). These days, a single queue feeds all tellers. (We exclude from consideration special-purpose tellers.) How does changing from multiple queues (MQ) to a single queue (SQ) affect customers? In particular, what is the effect on *average* waiting time?

To consider this question, assume arrival times t_i and service times S_i are fixed. We are changing the *order* of service. (Should there be a positive queue behind one teller when another teller becomes free, we assume that a customer will shift immediately to the idle teller.) With SQ, customers are served FIFO. With MQ, service times *in the order served* are a rearrangement of the S_i .

Suppose customer service times are i.i.d., independent of all else. Service times in the order served will be i.i.d., and the *distribution* of the number of customers in system will not change. That is, $\{N(t), t \geq 0\}$ under MQ is essentially the same process as under SQ. (The number in system processes are said to be *stochastically equivalent*.) Hence time-average L has not changed. As λ has not changed,

$$w = L/\lambda \text{ has not changed.}$$

This does not mean that customers are indifferent to the change. The waiting time *distribution* will change. In fact, from the FIFO property of SQ, it is easily shown that the *variance* of *delay* under SQ is smaller than under MQ, and also under any alternative of this nature, such as an SQ that operates LIFO.

Some queueing models are much more complex. A farmers' market may be viewed as a *queueing network*, where each arriving customer is served at some sequence of stands (stations), and then departs. LL applies to the arrival and departure of customers at the market, and also to the arrival and departure of customers at individual stations. This is an *open network*. In a *closed network*, customers move from station to station, but there are no arrivals to or departures from the system. For closed networks, LL holds at individual stations.

SAMPLE-PATH PROOF OF LITTLE'S LAW

Our intuitive explanation for LL in the section titled "Notation, Explanation, Applications" is the basis for a formal proof:

Proof. Motivated by Figs 1 and 2, we obtain the inequalities in Equation (5), where the sum on the left is over those waiting-time rectangles that have ended by T .

$$\sum_{\{i: t_i + W_i \leq T\}} W_i \leq \int_0^T N(t) dt \leq \sum_{i=1}^{\Lambda(T)} W_i. \quad (4)$$

Now divide Equation (5) by T and let $T \rightarrow \infty$. The right-hand expression has limit λw , which implies the left-hand expression has $\limsup \leq \lambda w$. LL follows if it has limit λw . Toward that end, we need two preliminary results. First, write

$$\frac{W_n}{n} = \frac{1}{n} \sum_{i=1}^n W_i - \left(\frac{n-1}{n}\right) \left(\frac{1}{n-1}\right) \sum_{i=1}^{n-1} W_i.$$

For finite w , this expression has limit $w - w = 0$ as $n \rightarrow \infty$. That is,

$$\lim_{n \rightarrow \infty} W_n/n = 0. \quad (5)$$

Finite λ implies $t_n \rightarrow \infty$ and hence $\Lambda(t_n)/t_n \rightarrow \lambda$ as $n \rightarrow \infty$. If the arrival times are distinct, $\Lambda(t_n) = n$; otherwise, $\Lambda(t_n) \geq n$, and we write

$$\frac{W_n}{t_n} = \frac{W_n}{n} \frac{n}{t_n} \leq \frac{W_n}{n} \frac{\Lambda(t_n)}{t_n}.$$

For finite λ and w and from Equation (6), we have

$$\lim_{n \rightarrow \infty} W_n/t_n = 0. \quad (6)$$

For any $\epsilon > 0$, Equation (7) implies that for some finite m and all $i > m$, $W_i < t_i \epsilon$ and $t_i + W_i < t_i(1 + \epsilon)$. Thus $t_i \leq T/(1 + \epsilon) \implies t_i + W_i \leq T$ for every $i > m$, which gives this *lower bound* on the left-hand expression in Equation (5):

$$\sum_{i=1}^{\Lambda\left(\frac{T}{1+\epsilon}\right)} W_i - \sum_{i=1}^m W_i \leq \sum_{\{i: t_i + W_i \leq T\}} W_i. \quad (7)$$

Now divide Equation (8) by T and let $T \rightarrow \infty$, noting that the second term on the left is a constant. The left-hand side has limit $\lambda w/(1 + \epsilon)$, which implies the right-hand side has $\liminf \geq \lambda w/(1 + \epsilon)$. Because ϵ can be arbitrarily small, this implies the $\liminf \geq \lambda w$. Combining with $\limsup$, the limit is λw , and we have Equation (3).

Some early proofs (but after Little [1]) assumed the system would empty from time to time. Little did not require that, nor do we,

aside from our convention that the system is empty initially (which can be dispensed with). To illustrate, suppose C_i arrives at $t_i = 2i$, with service time $S_i = 3$, $i \geq 1$, at a two-server system. It is easy to see that (draw the figure!) even though the system never empties, the limits are $\lambda = 1/2$, $w = 3$, and $L = \lambda w = 1.5$.

Now, let $\Lambda^d(t)$ be the number of departures by t . When Equation (6) holds, we have Equation (7). By the same method, it is easy to show that

$$\lim_{t \rightarrow \infty} \Lambda^d(t)/t = \lambda, \quad (8)$$

that is, the departure rate is equal to the arrival rate. (We do not require $w < \infty$; see following section.)

Technical Considerations; the Case $w = \infty$

In Figs 1 and 2, $\{W_i\}$ determines $\{N(t)\}$, but not the converse. It also turns out that when finite limits L and $\lambda > 0$ exist, w may not exist; for examples, see Ref. 2 and p. 289 of Ref. 3. In both cases, the waiting time average oscillates, and limit (Eq. 6) does not exist.

Suppose $0 < \lambda < \infty$ and w exist, with $w = \infty$. It would be nice to have $L = \infty$ as well, and this is known to be true for a variety of queueing models.

To deal with this question, suppose Equation (6) still holds, which gives Equations (7) and (8). Now divide Equation (8) by T . For $w = \infty$, the left-hand side $\rightarrow \infty$ as $T \rightarrow \infty$. When $0 < \lambda < \infty$, $w = \infty$, and Equation (6) holds, L is well defined, where

$$L = \infty.$$

For a single-server FIFO queue with finite average service time $E(S)$, where $\rho \equiv \lambda E(S) < 1$, it is easy to show that Equation (6) holds, even when $w = \infty$. However, this is not always true. For example, consider an ∞ -server queue with i.i.d. service times, so the $W_i = S_i$ are i.i.d. For i.i.d. W_i , $w < \infty$ w.p.1 if and only if Equation (6) holds w.p.1; see p. 239 of Ref. 4. The point is not whether $L = \infty$ in this example, but rather to question when it is valid to use Equation (6) to prove it.

STATIONARY VERSION OF LITTLE'S LAW

Queueing models are rarely so simple that either L or w can be found directly as sample-path averages. Instead, we find the distributions of N or W , or enough about them to find their means. This is usually done by a *stationary analysis*.

A substantial portion of the queueing literature is about continuous-time Markov-chain models, sometimes with complex structure. For a queueing network, we let $N_k(t)$ be the number of customers at station k at time t , and $N(t)$ be their sum over k . We replace exponential service with *phase-type* service, and so on. For positive-recurrent chains, stationary N exists, with distribution determined by the balance equations, and $L = E(N)$ w.p.1, even when infinite. In these models, $\lambda > 0$ (in open networks), and $w = L/\lambda$. Sometimes sophisticated techniques are required to determine positive recurrence and to solve for stationary distributions, or their means, or approximations of them, but we have changed the playing field from finding sample-path averages directly.

Sometimes, we find properties of W directly, and from them, properties of N . For a single-server queue with *renewal arrivals* (i.i.d. interarrival times) and i.i.d. service times (the $GI/G/1$ queue), FIFO delays D_i satisfy the recursion

$$D_{i+1} = \max\{D_i + S_i - T_i, 0\}, \quad i \geq 1, \quad (9)$$

where *interarrival time* $T_i = t_{i+1} - t_i$. Assume $0 < \lambda E(S) < 1$. By letting D_i and D_{i+1} in Equation (10) have the same distribution (a stationary analysis), we find approximations and bounds for the mean and other properties of D , W , and N .

Little's Law via Stationary Marked Point Processes

A (one-dimensional) *marked point process* (MPP) is a sequence $\{t_i, k_i\}$, $i \geq 1$, where $0 \leq t_1 \leq t_2 \leq \dots$ are the points, and the k_i are the marks. For queueing theory applications, the t_i are arrival times, so $\{t_i\}$ (the point process) is an arrival process, and for each i , k_i is something associated with arrival i ; in a

single-server queue, for example, it would be the service time of arrival i .

An MPP is called *stationary* MPP (SMPP) if $t_1 > 0$ and $\{\Lambda(t)\}$ has stationary increments, which means that for every t , the distribution of $\Lambda(t+h) - \Lambda(h)$ is independent of h . For an SMPP, it is easily shown that for all t , $E\{\Lambda(t)\} = \lambda t$, where $\lambda > 0$ is the arrival rate. For renewal arrivals, where $T_i = t_{i+1} - t_i$, $i \geq 1$, have distribution function F and mean $1/\lambda$, we get the corresponding SMPP by letting t_1 have *equilibrium* density function $f_e(u) = \lambda[1 - F(u)]$, $u \geq 0$.

$\{\Lambda(t)\}$ is *time* stationary. For some $\{\Lambda(t)\}$, we would like to determine the distribution of *event* (or *customer*) stationary $\{T_i\}$, and the converse. For renewal arrivals, this is easy, but in general, where the T_i are dependent, this is not the case. One of the major achievements of point-process theory was to *invert* (determine one from the other) the distributions of $\{\Lambda(t)\}$ and $\{T_i\}$ (the latter is called the *Palm* distribution), where the one we start with is stationary and ergodic. Originally, this was for *simple* arrival processes, where this means $T_i > 0$. Later, this was extended to allow $P(T_i = 0) > 0$ (batch arrivals).

We also have marks. Starting with stationary $\{T_i, W_i\}$, the corresponding $\{\Lambda(t), N(t)\}$ was constructed in Ref. 5 (and in earlier work referenced there), where $\{N(t)\}$ is stationary, and the stationary version of Little's Law

$$E(N) = \lambda E(W), \quad (10)$$

was shown, even when infinite, without appealing to the sample-path version.

Describing how the inversion or this construction is done is beyond our scope. In addition to Franken *et al.* [5], we cite Daley and Vere-Jones [6] for point-process theory, Sigman [7] for an empirical-inversion

approach, Miyazawa *et al.* [8] for more on Palm theory, and all four for a historical account and references.

Equation (11) appears to be very general. For example, we can view waiting times in some model as though they were generated by an ∞ -server queue, and set $W_i = S_i$, where the S_i are stationary and ergodic. However, this is somewhat misleading because a queueing *model* usually would consist of an arrival process, service requirements, and details about the service facility. Stationary $\{W_i\}$ has to be *constructed*. This is easy to do for a single-server queue, but for, say, a network of multiserver stations, we do not know how to do this, or even whether such a $\{W_i\}$ exists, without having some structure, such as regeneration points (in a general sense), or a Markov process that is Harris recurrent.

We now present a deterministic example where customer- and time-stationary processes are easily constructed independently.

Example 3. Consider a single-server queue with $t_1 = 1$, subsequent interarrival times that alternate, 1, 4, 1, 4, ... (so $\lambda = 1/2.5 = 0.4$), and constant service times $S_i = 2$. We plot $\{N(t)\}$ in Fig. 4.

When $T_i = 1$, C_i finds the system empty, and $W_i = 2$. Similarly, when $T_i = 4$, $W_i = 3$. These events alternate. We have jointly stationary $\{T_i, W_i\}$, where events $\{T_i = 1, W_i = 2\}$ and $\{T_i = 4, W_i = 3\}$ each has probability 1/2.

It is easy to see (as fractions of time) that stationary N has distribution

$$\begin{aligned} P(N = 0) &= P(N = 2) = 0.2, \text{ and} \\ P(N = 1) &= 0.6, \end{aligned} \quad (11)$$

Figure 4. Constructing stationary versions.

with $E(N) = 1.0$. From the distribution of $\{T_i, W_i\}$, $E(W) = 2.5$, and (of course!) $E(N) = \lambda E(W) = (0.4)(2.5)$.

Constructing $\{\Lambda(t)\}$ with stationary increments: As the arrival process is deterministic, its stationary version is completely determined by where the initial point $t_0 = 0$ falls. We call interarrival intervals either *long* (length 4) or *short* (length 1). If t_0 falls in a long, the time until the first arrival is uniformly distributed on $(0, 4)$, with subsequent interarrival times $1, 4, 1, 4, \dots$. If it falls in a short, the time until the first arrival is uniformly distributed on $(0, 1)$, with subsequent interarrival times $4, 1, 4, 1, \dots$. The probability that t_0 falls in a long is 0.8, which is the fraction of the real line that is covered by long intervals.

Selecting $t_0 = 0$ in this manner, we get waiting-time sequence $2, 3, 2, 3, \dots$ with probability 0.8 (t_0 falls in a long), and $3, 2, 3, 2, \dots$ otherwise. $\{W_i\}$ is *not* stationary. Except in special cases such as renewal arrivals, it is not possible for $\{N(t)\}$ and $\{W_i\}$ to be stationary simultaneously on the same sample space.

EXTENSION TO $H = \lambda G$; WORK

For Little's Law, the C_i (and unspecified system behavior) generate $\{W_i\}$ and $\{N(t)\}$, where C_i contributes W_i to the area under $\{N(t)\}$. We now present an extension, where the C_i may generate other discrete- and continuous-time processes that are related in the same way. We consider only the sample-path version, at sample point ω , and again omit writing ω explicitly.

For each C_i , we associate function $f_i(t)$, $t \geq 0$, where $\int_0^\infty |f_i(t)| dt < \infty$, and for some finite $l_i > 0$, $f_i(t) = 0$ for $t \notin [t_i, t_i + l_i)$. Now define

$$G_i = \int_0^\infty f_i(t) dt, \quad i \geq 1,$$

$$\text{and } H(t) = \sum_{i=1}^\infty f_i(t), \quad t \geq 0.$$

When $f_i(t) \geq 0$, G_i is the area under $\{H(t)\}$ contributed by C_i . Often, $l_i = W_i$. We define

customer and time averages, and λ as defined before

$$\bar{G} = \lim_{n \rightarrow \infty} \frac{1}{n} \sum_{i=1}^n G_i, \quad \text{and } \bar{H} = \lim_{T \rightarrow \infty} \frac{1}{T} \int_0^T H(t) dt.$$

The following is an important extension of LL:

Theorem 2 $[\bar{H} = \lambda \bar{G}]$. *If limits λ and $\bar{G}$ exist and are finite, and technical condition (TC): $l_i/t_i \rightarrow 0$ as $i \rightarrow \infty$, $\bar{H}$ exists, where*

$$\bar{H} = \lambda \bar{G}. \quad (12)$$

In the literature, the usual notation is " $H = \lambda G$," but we prefer to reserve H and G for the stationary version. For LL, $l_i = W_i$, and TC is implied by $w < \infty$. Without TC, some of the area contributed by C_i may occur so far in the future that, as i increases, some of it is "lost" in the limit, where, possibly

$$\bar{H} < \lambda \bar{G},$$

or $\bar{H}$ may not exist. However, TC is not necessary. For a necessary and sufficient condition, see Ref. 9, p. 178. The easily proven version here is widely applicable.

The same issue arises with LL when we have *multiple visits*; that is, the same customer visits the system many times, and we define W_i as the sum of C_i 's waiting times on all visits. Let C_i depart (for the last time) at $t_i + l_i$. If w is finite but TC does not hold, it is possible to have

$$L < \lambda w.$$

The so-called *counterexamples* to Little's Law have been constructed in this manner.

We sketch a proof of $\bar{H} = \lambda \bar{G}$, which is almost identical to that for LL. We assume $f_i(t) \geq 0$. When this is not the case, split the functions into their positive and negative parts, $f_i^+(t) = \max\{f_i(t), 0\}$ and $f_i^-(t) = -\min\{f_i(t), 0\}$, $t \geq 0$. Go through the steps below for the positive parts and the negative parts separately, and combine the results.

Figure 5. Work in system for a single-server queue.

When $f_i(t) \geq 0$, the bounds on the integral below are immediate:

$$\sum_{\{i: t_i + l_i \leq T\}} G_i \leq \int_0^T H(t) dt \leq \sum_{i=1}^{\Lambda(T)} G_i. \quad (13)$$

Now divide Equation (14) by T and let $T \rightarrow \infty$. The right-hand expression has limit $\lambda \bar{G}$, and the left-hand expression has $\limsup \leq \lambda \bar{G}$. To complete the proof, we obtain a lower bound on the left-hand expression in Equation (14). We already have $l_n/t_n \rightarrow 0$, and following the argument for Equation (7), we get $l_n/t_n \rightarrow 0$, as $n \rightarrow \infty$. Following the argument for Equation (8), we have the lower bound

$$\sum_{i=1}^{\Lambda\left(\frac{T}{1+\epsilon}\right)} G_i - \sum_{i=1}^m G_i \leq \sum_{\{i: t_i + l_i \leq T\}} G_i.$$

The remaining steps are the same as those for Equation (3), and we have proven Equation (13).

When $\lambda > 0$ and $\bar{G} = \infty$, and we still have $\text{TC}, \bar{H} = \infty$.

Work in System

After Little's Law, the most important applications of Equation (13) involve various representations of process $\{V(t)\}$, where $V(t)$, called *work in system* or just *work* at time $t \geq 0$, is the sum of the remaining service times of all customers in system at time t .

With the notation in the section titled "Notation, Explanation, and Applications," suppose we have a *single-server* queue with arrival times t_i and service times S_i .

$V(t)$ jumps by S_i at t_i , and where positive, decreases with slope -1 between jumps, because the remaining service time of any customer in service decreases at that rate. A typical sample path of $V(t)$ is shown as the heavy horizontal (where $V(t) = 0$) or slanted lines in Fig. 5.

When customers are served FIFO, the diagonal dotted lines show when the first two customers finish service. The vertical dotted line shows when C_2 enters service, and the time between t_2 and that line is D_2 . Similarly, D_3 (not shown) is easy to represent. The contribution of customer C_i to the area under $\{V(t)\}$ is a trapezoid that has a rectangular piece with area $D_i S_i$, and a triangular piece with area $S_i^2/2$. So for this example, $G_i = D_i S_i + S_i^2/2$, and from Equation (13)

$$E(V) = \lambda \left[\overline{DS} + \overline{S^2}/2 \right]. \quad (14)$$

To be consistent with our notation, " $E(V)$ " should be " $\bar{V}$." From the stationary version, however, it is also the mean of a stationary V . The *form* of Equation (15) does not require FIFO order of service, but only that customers are served to completion, without interruption. For example, it holds under LIFO and SJF. (While each customer still generates a trapezoid, the D_i would change. If we had LIFO in Fig. 5, D_3 would be the time between t_3 and the vertical dotted line.) Note that TC is the same as Equation (6) here, and is satisfied when $w < \infty$.

When we make additional assumptions, Equation (15) can be written in different ways. For example, when service times are i.i.d. and independent of the arrival process, the D_i and S_i are independent and

$\overline{DS} = dE(S)$; Equation (15) becomes

$$E(V) = \rho d + \lambda E(S^2)/2, \quad (15)$$

where $\rho = \lambda E(S)$. This includes FIFO and LIFO, but *not* SJF. When we also have Poisson arrivals (now an $M/G/1$ queue) and FIFO, $d = E(V)$ (from PASTA, see Ref. 10), and from Equation (16), we get

$$d = \lambda E(S^2)/2(1 - \rho), \quad (16)$$

which is the average delay in queue for this model. (As in Example 2, d is the same under LIFO; only the *argument* for Equation (17) requires FIFO.) When arrivals are not Poisson, and we can show either $d > E(V)$ or $d < E(V)$, then from Equation (16), we get a *bound* on d .

Equation (15) holds for multiserver queues, but the sample paths of $\{V(t)\}$ would change. When service times are i.i.d., Brumelle [11] used these ideas to obtain an important lower bound on d_c , the average delay in queue for a c -server system, in terms of the average delay for a corresponding fast single server; that is, a server with service times S_i/c .

Sometimes a queue operates under rules that give preferential treatment to some customers or classes of customers over others. This may permit interrupting service on one customer in order to serve another. Suppose we have *work conservation*, which means that the total time in service of every customer is rule invariant. For a *single-server* queue, this implies that the sample paths of $\{V(t)\}$, as in Fig. 5, are the same for all rules, as is $E(V)$. This fact plays an important role in the analysis of these rules. For many examples, see Ref. 3.

A RATE CONSERVATION LAW (RCL)

As with Little's Law and its extensions, the rate conservation law (RCL) by Miyazawa is of fundamental importance in queueing theory. We cite Miyazawa [12], a review article; his publications in this area go back to 1983. The theory of *level crossings* [13] is a special case.

As conceived by Miyazawa, RCL is a relation between the expected values of time-stationary and arrival-stationary quantities, as is the case for Little's Law in Equation (11). Sigman [14] showed that the sample-path version of RCL is equivalent to the corresponding version of $\overline{H} = \lambda \overline{G}$.

However, the starting points for these results (geometrically-appealing areas in one case, jumps and derivatives in the other) are quite different. In an application, one is often much easier and more intuitive to use than the other.

In this brief introduction, we present only the sample-path version of RCL.

Consider a sample path $\{Y(t, \omega), t \geq 0\}$ of some stochastic process at sample point ω . As before, we drop ω , writing $Y(t) = Y(t, \omega)$, and let $\mathbf{Y} = \{Y(t)\}$. We assume $\mathbf{Y}$ is right-differentiable for all t , and define

$$Y'(t) = \lim_{h \downarrow 0} [Y(t+h) - Y(t)]/h,$$

where we assume that $\mathbf{Y}'$ is right-continuous and has left-hand limits. Now $\mathbf{Y}$ may have discontinuities. Let "events" occur at points in an underlying point process (events could be arrivals), $0 < t_1 < t_2 < \dots$, where $r(t)$ is the number of points that occur by t , such that each discontinuity of $\mathbf{Y}$ occurs at one of these points. (We don't require $\mathbf{Y}$ to be discontinuous at every such point.) Define

$$-J_i = Y(t_i+) - Y(t_i-),$$

the size of the i th jump.

Then we have

$$\int_0^t Y'(u) du = Y(t) - Y(0) + \sum_{i=1}^{r(t)} J_i, \quad (17)$$

which simply means that the *change* in $\mathbf{Y}$ between 0 and t is the sum of the change while continuous plus the sum of the jumps.

Define the limits, when they exist, event rate λ , event average $\overline{J}$, and time average $\overline{Y'}$. Now divide Equation (18) by t and let $t \rightarrow \infty$. The following has been shown:

Theorem 3 [Sample-Path RCL]. When λ and $\bar{J}$ are finite, and $Y(t)/t \rightarrow 0$ as $t \rightarrow \infty$,

$$\bar{Y}' = \lambda \bar{J}. \quad (18)$$

(The stationary-version notation is to write $\bar{Y}' = E(Y')$ and $\bar{J} = E(J)$.)

It is easier to obtain Equation (15) via Equation (13) (it is immediate), rather than via RCL. On the other hand, for finding an expression for $P(V > v)$, for stationary work in system V , RCL is the better tool. See p. 664 of Ref. 14.

A DISTRIBUTIONAL LITTLE'S LAW

The stationary version of Little's Law raises this question: Is there a similar relation between the distributions of N and W , a *distributional* Little's Law?

In Example 2, we compared a bank under different rules of operation. Under both rules, the distribution of N is the same, but the distribution of W is different. There is no hope for a distributional law in a general setting. Nevertheless, we derive a law in the restricted setting of Haji and Newell [15]. For this result, further restricted to Poisson arrivals, with applications, see Keilson and Servi [16].

Let $t_0 = 0$ be a random time point, where $N(0) = N$ is stationary, and $\{\Lambda(t), -\infty < t < \infty\}$, has stationary increments. Number customers backward in time, where C_i occurs at $-t_i$, $0 \leq t_1 \leq t_2 \leq \dots$. So C_1 is the most recent arrival. We make the following assumptions:

- (a) Customers depart FIFO from the system,
- (b) $\{W_i\}$ is stationary, and for every i ,
- (c) W_i is independent of the arrival process after C_i arrives; in particular, it is independent of t_i , which is "how long ago" that customer arrived.

Thus, customer i is in the system at time $t_0 = 0$ if and only if $\{W_i \geq t_i\}$, and because of (a), these are the same events:

$$\{N \geq i\} = \{W_i \geq t_i\}, i \geq 1,$$

where (c) W_i and t_i are independent, and (b) $P(N \geq i) = P(W \geq t_i)$, where W is an arbitrary stationary waiting time, independent of every t_i . The event $\{W \geq t_i\}$ means that at least i arrivals occur in interval $[-W, 0]$, where W is independent of $\{\Lambda(t)\}$, and the probability of this event does not depend on the interval location. We have

Theorem 4 [A Distributional Little's Law, (DLL)]. Under assumptions (a)–(c),

$$N \text{ has the same distribution as } \Lambda(W), \quad (19)$$

where $\{\Lambda(t)\}$ and W are independent.

We now introduce some new quantities to compare this result with another. For a queueing system, let N_a and N_d be, respectively, the stationary number of customers in system *found by an arrival*, and *left behind by a departure*. It is easily shown that, in general, N_a and N_d have the same distribution. On the other hand, it is usually the case that N_a and N have different distributions and means. For simplicity, assume interarrival times $T_i > 0$ (no batches). Let $\{\Lambda_c(t)\}$ be the *customer-stationary* arrival process, which begins with an arrival at $t_0 = 0$, and $\Lambda_c(t)$ is the number of arrivals in interval $(0, t]$. When we have assumption (a), N_d is the number of arrivals during the departing customer's waiting time, and when we also have renewal arrivals (Poisson arrivals is a special case),

$$N_d \text{ has the same distribution as } \Lambda_c(W), \quad (20)$$

where $\{\Lambda_c(t)\}$ and W are independent. While Equation (21) is similar to Equation (20), it is not as useful. Usually, $E\{\Lambda_c(t)\} \neq \lambda t$ and $E(N_d) = E\{\Lambda_c(W)\} \neq \lambda E(W)$.

To illustrate, consider a single-server queue, where $t_i = 10i$ and $S_i = 9$ for all i (a $D/D/1$ queue). Stationary waiting time $W_i = 9$, a constant. As fractions of time, it is easy to see that N is either 0 or 1, with distribution

$$P(N = 0) = 0.1 \text{ and } P(N = 1) = 0.9. \quad (21)$$

We have $\lambda = 0.1$ and $E(N) = \lambda E(W)$, but $N_a = N_d = \Lambda_c(W) = 0$. For $\{\Lambda(t)\}$, t_1 (backward in time) is uniformly distributed on $(0, 10)$. C_1 is in the system at $t_0 = 0$ if and only if $\{t_1 \leq 9\}$, and $\Lambda(W) = 1$. $\Lambda(W)$ has distribution (Eq. 22); DLL holds. This is a special case of a FIFO $GI/G/1$ queue, where DLL also holds.

Confusion between $\{\Lambda(t)\}$ and $\{\Lambda_c(t)\}$ may be partly responsible for the following *incorrect* “intuitive” and “elementary” explanation of the stationary version of Little’s Law that has appeared several times in the literature: (i) $E(N_a) = E(N_d)$ and (ii) $E(N_d) = \lambda E(W)$.

While (i) is true, there are several problems with this argument. Implicit in (ii) is FIFO, as in (a) in Theorem 4. That is merely a restriction. More serious is that (ii) is often false, as in the elementary example above. Also serious is the implicit equating of N_a and N . We are left with

$$L = E(N) \neq E(N_a) = E(N_d) \neq \lambda E(W). \quad (22)$$

For the $M/G/1$ queue, both inequalities in Equation (23) are equalities, the first from PASTA (N and N_a have the same distribution); for the second, a Poisson process has stationary and independent increments ($\{\Lambda(t)\}$ and $\{\Lambda_c(t)\}$ are equivalent). In this case, the explanation is correct, but it is neither intuitive nor elementary.

Now return to DLL. When does it hold? Condition (a) holds for single-server queues when customers in queue are served FIFO. It holds for a tandem (series) arrangement of single-server queues. It holds for multiserver queues under FIFO and constant service. Looking only at the queue, there is a corresponding relation between the number of customers in queue and the delay in queue. It holds for multiserver queues under FIFO, with a general service distribution. There are other examples for priority classes in what are called *priority queues*.

Condition (c) appears to require renewal arrivals, which includes the Poisson process, but not (say) the typical arrival process at the second station of a tandem queue. There is an exception to this requirement when there are an infinite number of servers. DLL does not hold in Example 3.

The DLL is very useful when it applies, but unlike the ubiquitous LL, the conditions for it to hold are rather restrictive.

BRIEF HISTORY AND LITERATURE REVIEW

Little’s Law was believed to be true long before 1961. In p. 75 of Ref. 17, Morse noted that it holds for every model he was aware of, and challenged someone to either come up with a general proof or a counterexample. Unfortunately, this pre-1961 status inhibited the use of LL as a tool in analysis of queueing models.

We have emphasized the sample-path version because it is the easiest to understand and prove, and it holds in situations when there may be no stationary version. Viewed this way, it is a conservation law (of area). Furthermore, it is rare in an application to use the full stationary version in Equation (11). Instead, a stationary analysis is performed to determine properties of *one* of the stationary distributions sufficient to find, approximate, or make other statements about its mean. The sample-path version then gives us the other.

At first glance, Little’s formulation seems to be sample-path, but it is not, as it relies on stochastic properties to obtain limits. There also is a flaw in the formulation, as noted in Ref. 18 and elsewhere. In 1967, Jewell [19] proved LL for (classically) regenerative processes where the system empties from time to time, and a new cycle begins. Thus over a cycle, Equation (1) is exact! (Shortly thereafter, several authors either proved LL or gave intuitive explanations for systems that empty periodically.) What Jewell showed may be viewed as a sample-path result and may have provided intuition for what followed. However, his conditions are very restrictive. Stidham has the first sample-path proof [20], and in 1974 [2], a proof similar to the one here.

What is now usually called $H = \lambda G$ has a similar history. Brumelle [18] proved it in 1971 in a stochastic setting similar to Little. He also obtained the important Equation (15). Heyman and Stidham [21] has a sample-path proof in 1980 similar to the one presented here. Brumelle’s result is not the

equivalent stationary version (Eq. 11) in the section titled "Stationary Version of little's Law." See the references there.

There are too many related results to discuss in the space we have. Here are three. For $H = \lambda G$, a customer's contribution is an integral, so it accumulates gradually. This has been extended to allow "lumps" at certain times. Often, a model is simulated to estimate (say) Q or d , and direct (straightforward) estimators of each, $\hat{Q}$ or $\hat{d}$, are available. From LL, an *indirect* estimator of (say) Q is $\lambda \hat{d}$. The statistical efficiency of indirect estimators was investigated in Law [22], and by others later. Finally, there are also central-limit-theorem versions of these results.

For more on these and other results, many other references, and discussion of the literature, see Refs 9, 23, and 24.

LOAD-SHARING SYSTEMS

ISHA DEWAN
Indian Statistical Institute, New
Delhi, India

UTTARA V. NAIK-NIMBALKAR
University of Pune, Pune,
Maharashtra, India

In Ref. 1, the authors refer to an article in the New York Times by Glanz and Lipton [2] pertaining to the collapse of the twin towers of the World Trade Center on September 11, 2001. The World Trade Center had its weight resting mainly on interior columns and also on the pinstripe columns at the exterior. A support system at the top of the building connected these columns at the facade to the core. When the airplanes hit the top of the building, the support system at the top shifted the load on the damaged columns to the undamaged columns. Because of this load sharing, the towers did not collapse immediately after they were hit by the airplanes. This saved thousands of lives.

In Ref. 3, the authors refer to the power crisis in the city of Auckland, New Zealand. At the beginning of 1998, the city received electricity from a single supplier via four power cables. Two of them were 40 years old. One cable failed on January 20 due to extremely hot and dry conditions, the second failed on February 9. This led to increased load on the remaining cables, which too failed on February 19 and 20, leaving large parts of the city without power.

In general, in any multicomponent system, the failure of one component can affect the working of the remaining components. But the effect varies according to the load-sharing rule, which tells us how the “load” of the failed component is distributed among the other surviving components of the system. An *equal load-sharing* system is subject to a constant load. Once a component fails, the system load is spread equally among the surviving components. A common example is a parallel system where the k component

lifetimes are independent and identically distributed (i.i.d.) random variables with constant failure rate θ . When the first component fails, then each of the surviving components has failure rate $\frac{k}{k-1}\theta$, on second failure the remaining $k-2$ components have failure rate $\frac{k}{k-2}\theta$, and so on. Under the *monotone load-sharing* rule the load on the surviving components increases as other components fail, that is, the greater the number of failures, the larger is the load on the surviving components. Under *local load sharing*, the effect of the failure of a component is relatively more on certain components (usually the neighbors) and is generally less for components placed at a greater distance from the surviving component.

Sometimes the failure of the first component shortens the residual life of the remaining components. This can lead to an error in the estimation of the system reliability. In load-sharing models, the failure rate of the components depends on whether the other components in the system are functioning or not.

The earliest work on load-sharing models is due to Daniels [4] and Rosen [5]. They observed that yarns and cables in a bundle fail only when the last fiber (or wire) in the bundle breaks. A bundle of fibers can be considered as a parallel system (see also ***Parallel Configurations***) subject to a constant tensile load. After one fiber breaks yarn bundles or untwisted cables tend to spread the stress load uniformly on the remaining unbroken fibers. This is the equal load-share rule under which the load of the failed component is distributed equally among the remaining working components.

Apart from textile industry, such model arises in manufacturing where a part can be considered failed only when the entire set of welded joints that holds the part together fails. However, the failure of one or two joints can increase the stress on the remaining joints.

In the life testing of roller bearings, two test bearings are run simultaneously in a

given machine. The failure of the first bearing leads to exfoliation of material from the bearing rolling paths. This could affect the oil supply shared by the two test bearings with metallic particles. This results in the early failure of the second bearing. Sometimes the failure is not immediately detected but the vibration level increases because of the first failure. This could damage the rolling path of the second bearing.

Another illustration discussed by McCool [6] is for the ink-jet printer elements. These units contain about 400 heating elements. These elements dispense ink which is used for character formation and their failure leads to poor printing quality. One normally tests only till the first heater on each of the elements fails as the first failure affects failure of the subsequent heaters.

This phenomenon can also be seen on airplanes. A small airplane can function on one jet engine, whereas two engines are required for a big airplane. In order to increase reliability, small airplanes have two functioning engines and big airplanes have four functioning engines. The extra engine shares the load. This helps in reducing the failure rate of the engines.

In all the above examples, the failure of the first component adversely affects the system performance. However, in some cases, the failure of the first component has a beneficial effect on the system performance. For example, the detection of a bug in a software can help in the detection of other bugs. Once a critical fault in the software has been detected, it can help in finding other bugs that had not yet been undetected.

Drummond *et al.* [7] carried out a study in a vertebrate species showing that selective deaths due to food shortage result in surviving offspring receiving an increased share of an undiminished food supply. They observed littermates of the domestic rabbit *Oryctolagus cuniculus* and found that after individual baby rabbits died, the total daily milk weight obtained by the litter continued to be the same. Hence the surviving baby rabbits consumed more milk and showed greater growth.

Kim and Kvam [1] observed that such models also arise in sampling techniques. Suppose the total resources allocated toward

finding a finite set of items is fixed. Once one item is detected, resources can be redistributed to finding the remaining items.

Murthy and Nguyen [8] and Murthy and Wilson [9] studied a two-component parallel system (see also **Parallel Configurations**) where the failure of the first component leads to increased failure of the second component with probability p and does not effect the failure of the second component with probability $1 - p$. This is analogous to the Brown and Proschan (1983) model for repairable systems with imperfect repair.

Bebbington *et al.* [3] considered the general setup where the failure of the first component does not effect the hazard function of the other components immediately, but affects its conditional time to failure. They obtained nonparametric estimators of the failure rate function and the mean residual life function under this general setup.

Physicists have been studying load-sharing models under the study of fiber bundles. For some recent work, see Pride and Toussaint (2002), Bhattacharyya, Pradhan and Chakrabarti (2003) and Kang, Jo, Choi, Choi and Yoon (2007).

MODELS AND STATISTICAL INFERENCE

Here, we discuss several parametric and semiparametric models proposed for studying load-sharing systems over the last four decades, and discuss the related problems of estimation and testing of parameters.

Gross *et al.* [10] observed that two-organ subsystems in human body typically exhibit load-sharing phenomenon. If one organ fails, the surviving organ is usually subject to higher failure rate. If a patient gets his kidney removed because of some illness, then the second kidney shows a higher failure rate. However, if a kidney is removed because of an accident, then the second kidney may not exhibit an increased failure rate. The authors develop a survival distribution for such two-organ systems. They assume that if one organ fails, then the other organ has a higher failure rate. However, failure rates of both components are assumed to be constant.

Gross *et al.* [10] considered the following setup. The failure rate of each organ initially is a constant λ_0 . After the failure of one organ, the failure rate of the other organ is a constant $\lambda_1 \geq \lambda_0$. When $\lambda_1 \neq 2\lambda_0$, then the probability that the individual survives beyond time t is

$$S(t) = e^{-2\lambda_0 t} + \frac{2\lambda_0}{\lambda_1 - 2\lambda_0} (e^{-2\lambda_0 t} - e^{-\lambda_1 t}), \quad t \geq 0. \quad (1)$$

When $\lambda_1 = 2\lambda_0$, the density function of failure time is the convolution of two densities with the same parameter. Further, if $\lambda_1 = \lambda_0 = \lambda$ (say), it means that the failure of one organ does not affect the functioning of the other organ. In this case,

$$S(t) = e^{-\lambda t} (2 - e^{-\lambda t}), \quad t \geq 0, \quad \lambda > 0. \quad (2)$$

The authors obtained maximum likelihood estimators (MLEs) for the case $\lambda_1 \geq \lambda_0$. Since the MLEs cannot be expressed in a closed form, they used the Newton–Raphson method and the method of scoring to get iterative solutions. They concluded that both the methods gave similar estimates and the average number of iterations required were 3.2 for Newton–Raphson method and 4.0 for the scoring method. The method of moment estimate of λ_1 is biased (see also **Estimating Failure Rates and Hazard Functions**).

An m -out-of- k load-sharing system is considered in Refs 11–14. A general model is specified by considering arbitrary continuous distribution functions $F_1, F_2, \dots, F_k$. Before a failure, the k failure times are assumed to be i.i.d. with F_1 as the common distribution function. The first-component failure time is then the minimum of these k i.i.d. random variables. Upon the $(i-1)$ th ($i \geq 2$) component failure, conditionally given the $(i-1)$ th failure time z , the remaining $k-i+1$ working components are assumed to be i.i.d. random variables with the common distribution function

$$\frac{F_i(\cdot) - F_i(z)}{1 - F_i(z)}, \quad 2 \leq i \leq k. \quad (3)$$

The next component failure time is the minimum in the sample of the $k-i+1$ i.i.d.

random variables with distribution function given in Equation (3).

As a particular case of the above model, they modeled F_i by

$$F_i(t) = 1 - (1 - F(t))^{\alpha_i}, \quad 1 \leq i \leq k, \quad (4)$$

where F is an absolutely continuous distribution function and $\alpha_1, \alpha_2, \dots, \alpha_k$, are positive real numbers. With this model, after the $(i-1)$ th ($i \geq 2$) component failure, the hazard rate of the working components is $\alpha_i f / (1 - F)$, where f denotes the density function of F . Before any failure, the hazard rate is $\alpha_1 f / (1 - F)$.

For an exponential distribution F , the reliability of an m -out-of- k load-sharing system defined by Equations (3) and (4) is studied in Ref. 15.

The MLEs for model parameters $\alpha_1, \alpha_2, \dots$ for a known distribution F are obtained in Refs 12 and 13. Lifetimes of all the $k-m+1$ components that fail till the system fails are observed sequentially. These ordered observations are called *sequential order statistics*. Let $\{x_{i(j)}; 1 \leq j \leq k-m+1, 1 \leq i \leq n\}$ be the observed sequential failure times of components of n identical and independent systems. Then the likelihood is

$$\begin{aligned} L(\alpha_j, j = 1, \dots, k-m+1; F) &= \left(\frac{k!}{(m-1)!} \right)^n \left(\prod_{j=1}^{k-m+1} \alpha_j \right)^n \\ &\quad \left(\prod_{i=1}^n \prod_{j=1}^{k-m} (1 - F(x_{i(j)}))^{p_j} f(x_{i(j)}) \right) \\ &\quad \times \prod_{i=1}^n (1 - F(x_{i(k-m+1)}))^{p_{k-m+1}} \\ &\quad f(x_{i(k-m+1)}), \end{aligned} \quad (5)$$

where $p_j = (k-j+1)\alpha_j - (k-j)\alpha_{j+1} - 1$, $1 \leq j \leq k-m$ and $p_{k-m+1} = m\alpha_{k-m+1} - 1$.

The MLEs of $\alpha_1, \alpha_2, \dots, \alpha_{k-m+1}$ are

$$\hat{\alpha}_1 = -\frac{n}{k} (\log \prod_{i=1}^n (1 - F(x_{i(1)})))^{-1},$$

and

$$\hat{\alpha}_j = -\frac{n}{k-j+1} \left(\log \prod_{i=1}^n \frac{1-F(x_{i(j)})}{1-F(x_{i(j-1)})} \right)^{-1},$$

$$2 \leq j \leq k-m+1.$$

The following properties of the corresponding MLEs, also denoted by $\hat{\alpha}_1, \hat{\alpha}_2, \dots, \hat{\alpha}_{k-m+1}$, are established in Ref. 13.

Theorem 1.

- (i) *The MLEs $\hat{\alpha}_1, \hat{\alpha}_2, \dots, \hat{\alpha}_{k-m+1}$ are jointly independent.*
- (ii) *$\hat{\alpha}_j$ has an inverted gamma distribution with parameters n and $(1/(n\alpha_j))$, $1 \leq j \leq k-m+1$.*
- (iii) *$\hat{\alpha}_j \rightarrow \alpha_j$, a.s. as $n \rightarrow \infty$, $1 \leq j \leq k-m+1$.*
- (iv) *$\sqrt{n}(\hat{\alpha}_j/\alpha_j - 1)$ converges in distribution as $n \rightarrow \infty$ to a standard normal random variable, $1 \leq j \leq k-m+1$.*

For the model specified by Equations (3) and (4), three test procedures are suggested in Ref. 14 for testing the hypothesis

$$H_0 : \alpha_1 = \dots = \alpha_{k-m+1}$$

against the alternative

$$H_1 : \exists i \neq j, i, j \in \{1, 2, \dots, k-m+1\},$$

such that $\alpha_i \neq \alpha_j$.

The null hypothesis H_0 corresponds to an m -out-of- k system with i.i.d. components, that is, the failure of a component does not affect the failure of the other components. The failure rate of each component in this case remains $\alpha_1 f(t)/(1-F(t))$. The alternative H_1 corresponds to what the authors refer to as a *sequential m -out-of- k system*, where failure of a component does affect the failure rate of the surviving components.

Test I: Likelihood Ratio Test Let

$$Q = \frac{\sup_{\alpha_1=\dots=\alpha_{k-m+1}} L(\alpha_j, j=1, \dots, k-m+1; F)}{\sup_{\alpha_1, \dots, \alpha_{k-m+1}} L(\alpha_j, j=1, \dots, k-m+1; F)},$$

where $L(\alpha_j, j=1, \dots, k-m+1; F)$ is as in Equation (5). The hypothesis H_0 is rejected at level of significance α if $Q^{n(k-m+1)} \leq z_\alpha$. The authors provide values for the quantiles z_α for $\alpha = 0.01$ and $\alpha = 0.05$, for $r = 2, 3$ and 5 and $n = 1, 2, \dots, 10$. They suggest using chi-square approximations for large sample sizes.

Let $\hat{\beta}_j = n/\hat{\alpha}_j$, $1 \leq j \leq k-m+1$, where the $\hat{\alpha}_j$'s are the MLEs of α_j 's. Then, from Theorem 1, it follows that under the null hypothesis, the random variables $\hat{\beta}_1, \hat{\beta}_2, \dots, \hat{\beta}_{k-m+1}$ are independently and identically gamma distributed with parameters n and α_1^{-1} . The next two tests are based on this result.

Test II: Hartley's Test Let $\hat{\beta}_{(1)} \leq \hat{\beta}_{(2)} \leq \dots \leq \hat{\beta}_{(k-m+1)}$ be the order statistics corresponding to $\hat{\beta}_1, \hat{\beta}_2, \dots, \hat{\beta}_{k-m+1}$. The test procedure suggested is to reject H_0 , if the ratio $\hat{\beta}_{(1)}/\hat{\beta}_{(k-m+1)} \leq z_\alpha$, where z_α is determined by $P_{H_0}(\hat{\beta}_{(1)}/\hat{\beta}_{(k-m+1)} \leq z_\alpha) = \alpha$. The authors provide values of z_α for $\alpha = 0.01$ and $\alpha = 0.05$, $k-m+1 = 2, 3$, and 5 and $n = 1, 2, \dots, 10$.

Test III: The third test for the above hypothesis is based on the following statistic

$$B = \hat{\beta}_1 / \left(\sum_{j=1}^{k-m+1} \hat{\beta}_j \right),$$

which under H_0 has a Beta distribution on (0,1) with parameters n and $(k-m)n$. The hypothesis H_0 is rejected at level α if either

$$B \leq z_{\alpha/2} \text{ or } B > z_{1-\alpha/2},$$

where $z_{\alpha/2}$ and $z_{1-\alpha/2}$ are determined by

$$P(B \leq z_{\alpha/2} | H_0) = \alpha/2 \quad \text{and}$$

$$P(B > z_{1-\alpha/2} | H_0) = \alpha/2.$$

Kim and Kvam [1] considered k -component parallel system (see also **Parallel Configurations**). Initially, the components

are identically distributed with failure rate θ . After the first failure, the failure rate of the remaining $(k-1)$ components changes to $\gamma_1\theta, \gamma_1 > 0$. After the second failure, the failure rate of remaining $k-2$ components changes to $\gamma_2\theta$, and so on. Suppose there are n such systems. Let X_{ij} denote the lifetime of the j th component in the i th parallel system. Let

$$T_{ij} = X_{ij} - X_{i,j-1}, i = 1, 2, \dots, n, j = 1, \dots, k$$

denote the time between the j th failure and $(j-1)$ th failure of the i th system. Then, the likelihood function of the i th system is

$$\begin{aligned} L_i(\theta, \underline{\gamma} \mid t_{i1}, t_{i2}, \dots, t_{ik}) \\ = k! \theta^k \prod_{j=1}^{k-1} \gamma_j \exp \left(-\theta \sum_{j=1}^k (k-j+1) \gamma_{j-1} t_{ij} \right), \\ \text{with } \gamma_0 \equiv 1. \end{aligned} \quad (6)$$

The likelihood function based on n samples is,

$$\begin{aligned} L(\theta, \underline{\gamma} \mid \underline{T}) &= (k!)^n \theta^{nk} \left(\prod_{j=1}^{k-1} \gamma_j \right)^n \\ &\times \exp \left(-\theta \sum_{i=1}^n \sum_{j=1}^k (k-j+1) \gamma_{j-1} t_{ij} \right) \end{aligned} \quad (7)$$

where

$$\underline{T} = \{t_{ij}, 1 \leq j \leq k, 1 \leq i \leq n\}, \gamma > 0.$$

Then, the MLEs $(\hat{\theta}, \hat{\gamma})$ are solutions of the equations

$$\theta = \frac{nk}{\sum_{i=1}^n \sum_{j=1}^k (k-j+1) \gamma_{j-1} t_{ij}} \quad (8)$$

and

$$\begin{aligned} \gamma_{j-1} - \frac{\sum_{i=1}^n \sum_{j=1}^k (k-j+1) \gamma_{j-1} t_{ij}}{K \sum_{i=1}^n (k-j+1) t_{ij}} = 0, \\ j = 2, 3, \dots, k. \end{aligned} \quad (9)$$

Theorem 2. As $n \rightarrow \infty$, $\sqrt{n} \{(\hat{\theta}, \hat{\underline{\gamma}})' - (\theta, \underline{\gamma})'\}$ converges to a k -parameter Gaussian distribution with mean $\underline{Q}_k$ and covariance matrix Σ , where

$$\Sigma = \begin{pmatrix} \theta^2 & -\theta \underline{\gamma}' \\ -\theta \underline{\gamma}', & D(\underline{\gamma}^2) + \underline{\gamma} \underline{\gamma}' \end{pmatrix}$$

and $D(\underline{\gamma}^2)$ is the diagonal matrix $(\gamma_1^2, \dots, \gamma_{k-1}^2)$.

If the components' lifetimes were i.i.d. exponential variables, the asymptotic variance for $\hat{\theta}$ would be θ^2/k . In case of parallel systems, this is k times larger in size.

As discussed earlier, under equal load sharing, a constant total system load is divided equally among all working components. In this case, $\gamma_i = \frac{k}{k-i}$, $i = 1, \dots, k-1$. This generates another set of i.i.d. exponential data.

Under monotone load-share rule, a component failure results in increase in the workload of other components, and hence the failure rate might increase. Suppose $1 \leq \gamma_1 \leq \gamma_2 \leq \dots \leq \gamma_k$. The conditional likelihood between the $(j-1)$ th and j th failure is given as

$$L_j(\alpha_j) = (k-j+1) \alpha_j \exp(-(k-j+1) t_j \alpha_j)$$

where $\alpha_j = \gamma_{j-1} \theta$, $j = 1, \dots, k$,

where $\alpha_j = \gamma_{j-1} \theta$, $j = 1, \dots, k$. Then $\underline{\alpha} = (\alpha_1, \dots, \alpha_k)$, with $\alpha_1 = \theta$ is isotonic if and only if γ is isotonic.

Then Kim and Kvam [1] obtained MLEs of the parameters subject to $\alpha_1 \leq \alpha_2 \leq \dots \leq \alpha_k$. If one were to test $H_0 : \gamma_1 = \gamma_2 = \gamma_{k-1}$ against the alternative that all γ s are not equal, then,

one would use likelihood ratio-based techniques for hypotheses testing. One could also find confidence intervals for any combination of the failure rate θ and load-sharing parameters $\underline{\gamma}$. For large samples, the approximate $(1 - \alpha)$ confidence ellipsoid for $(\theta, \underline{\gamma})$ is

$$(\hat{\underline{\beta}} - \underline{\beta})' I_0^{-1} (\hat{\underline{\beta}} - \underline{\beta}) \leq \chi_{k, \alpha}^2. \quad (10)$$

where $\hat{\underline{\beta}}$ is the MLE of $\underline{\beta} = (\theta, \underline{\gamma})$. I_0 is the information matrix.

However, if the alternative indicates monotone load sharing $\gamma_1 \leq \gamma_2 \leq \dots \leq \gamma_{k-1}$, one can consider a likelihood ratio statistic where the MLEs are found using isotonic regression. In this case, under H_0 , the test statistic would have a chi-square distribution (a mixture of chi-square distributions). For details, see Ref. 1.

Extension of these likelihood-based techniques to Weibull, lognormal, and normal lifetimes would be difficult to handle analytically.

However, McCool [6] proposed a test procedure to test the hypothesis that the time to the second failure is not affected by the occurrence of the first failure. He assumes that the failure time follows a two-parameter Weibull distribution.

$$\bar{F}(t) = \exp \left[- \left(\frac{t}{\eta} \right)^\beta \right], \quad t \geq 0. \quad (11)$$

The scale parameter η has the same units as those in which lifetime is measured. It was observed that for a given value of the scale parameter, the variance decreases with increase in the value of β .

Suppose for each system we observe the first two failure times denoted by $X_{i(1)}$ and $X_{i(2)}$, respectively. Let $Z_i = \frac{X_{i(2)}}{X_{i(1)}}$, $i = 1, 2, \dots, n$.

Then on the basis of a random sample of size n from Equation (11), the MLE of the shape parameter β is the solution of the following nonlinear equation:

$$\left(\sum_{i=1}^n t_i^{\hat{\beta}_1} \right) \left(\frac{1}{\hat{\beta}_1} + \frac{1}{n} \sum_{i=1}^n \ln t_i \right) - \sum_{i=1}^n t_i^{\hat{\beta}_1} \ln t_i = 0. \quad (12)$$

The density of the ratio Z is given by

$$f(z) = \frac{n(n-1)\beta z_j^{\beta-1}}{[1 + (n-1)z^\beta]^2}, \quad z > 0. \quad (13)$$

Then, the MLE of the shape parameter β based on a random sample of size n from Equation (13) is the solution of the following equation:

$$\frac{1}{\hat{\beta}_2} + \frac{1}{n} \sum_{i=1}^n \ln z_i - 2 \frac{(k-1)}{n} \times \sum_{i=1}^n \frac{z_i \hat{\beta}_2 \ln z_i}{[1 + (k-1)z_i \hat{\beta}_2]} = 0. \quad (14)$$

If the null hypothesis is not true then, $\hat{\beta}_2$ obtained in Equation (14) will be larger than $\hat{\beta}_1$ obtained in Equation (12) because of reduced variability.

Under H_0 , the distribution of $LS_1 = \frac{\hat{\beta}_2}{\hat{\beta}_1}$ depends only on the sample size n and number of units in each system k . Hence it is distribution free.

McCool [6] obtained the percentiles for the distribution of LS_1 for $k = 2$ and He also found the power of the test when the underlying distribution is Weibull with the same shape parameter β , but the scale parameter has been reduced by a factor c .

Kvam and Pena [16] generalized the ideas of Kim and Kvam [1] with constant failure rate θ to arbitrary failure rate $r(x)$. They considered a system with k identical components and consider the equal load-sharing rule. Until the first-component failure, the failure rate of each of the k components of the system equals $r(x)$, called the *baseline failure rate* (see also **Estimating Failure Rates and Hazard Functions**). Upon the first failure, the failure rate of the $k-1$ remaining components becomes $\gamma_1 r(x)$. After the second failure, the failure rate of the $k-2$ surviving components changes to $\gamma_2 r(x)$, and so on. The failure rate of the last remaining component is $\gamma_{k-1} r(x)$. The main aim of their paper is to estimate the baseline component failure time distribution $F(\cdot)$ and the hazard function $R(\cdot)$ corresponding to the failure rate $r(x)$. The

data consist of observations on component failure times of n independent and identical systems over an observation period $[0, \tau]$, where τ could be random. For $i = 1, 2, \dots$, let $X_{i(1)} < X_{i(2)} < \dots < \tau$ be the successive component failure times for the i th system. They use the counting process theory to obtain the estimators and establish their asymptotic properties. Let $N_i(t) = \sum_{j=1}^k I(X_{i(j)} \leq t)$ and $Y_i(t) = (k - N_i(t-))I(\tau \geq t)$. The likelihood based on the observed data $\{(N_i(t), Y_i(t), 0 \leq t \leq \tau); i = 1, 2, \dots, n\}$ is given by

$$L(R(\cdot), \gamma) = \left\{ \prod_{i=1}^n \prod_{0 \leq u \leq \tau} [Y_i(u) \gamma [N_i(u-)] dR(u)] dN_i(u) \right\} \times \exp \left\{ - \int_0^\tau Y_i(u) \gamma [N_i(u-)] dR(u) \right\}, \quad (15)$$

where the second product denotes the product integral and

$$\gamma [N_i(u)] = \sum_{j=0}^{k-1} \gamma_j I(N_i(u) = j).$$

For a fixed γ , the generalized Nelson–Aalen estimator for R is then given by

$$\hat{R}(s, \gamma) = \int_0^s \frac{J(u) dN(u)}{\sum_{i=1}^n Y_i(u) \gamma [N_i(u-)]}. \quad (16)$$

For unknown γ , the profile likelihood for γ is obtained by substituting $\hat{R}(s, \gamma)$ for R in Equation (15), which is

$$L_p(s; \gamma) = \prod_{i=1}^n \prod_{0 \leq u \leq s} \left[\frac{Y_i(u) \gamma [N_i(u-)]}{\sum_{l=1}^n [Y_l(u) \gamma [N_l(u-)]]} \right] N_i(u). \quad (17)$$

This profile likelihood is maximized with respect to γ to obtain its estimator $\hat{\gamma}$, which is then plugged in $\hat{R}(s, \gamma)$ of Equation (16) to obtain the semiparametric estimator $\hat{R}(s)$ of $R(s)$. The estimator of the survival function $\bar{F}$

is $\hat{\bar{F}}(s) = \prod_{0 \leq u \leq s} [1 - \hat{R}(du)]$. The asymptotic properties of the estimators established in Ref. 16 are stated in the following theorem. First, some notations are introduced.

$$Q_{i,j}(t) = (Y_i(t) I(N_i(t-) = j), j = 0, 1, \dots, k-1; i = 1, 2, \dots, n,$$

$$Q_i(t) = (Q_{i,0}(t), \dots, Q_{i,k-1}(t))', i = 1, 2, \dots, n.$$

$$Q(t) = \left(\sum_{i=1}^n Q_{i,0}(t), \sum_{i=1}^n Q_{i,1}(t), \dots, \sum_{i=1}^n Q_{i,k-1}(t) \right)'$$

$$q(t) = (E(Q_{1,0}(t)), E(Q_{1,1}(t)), \dots, E(Q_{1,k-1}(t)))$$

and

$$\rho(t; \gamma) = E \left[\sum_{i=1}^n \gamma * Q_i(t) \right] / E[\gamma' Q(t)] \\ = \gamma * q(t) \times (\gamma' q(t))^{-1}.$$

Theorem 3. If $\{(N_i(\cdot), Y_i(\cdot), i = 1, 2, \dots, n)\}$ are i.i.d and $\inf_{0 \leq u \leq \tau} \sum_{j=0}^{k-1} (k-j) \gamma_j P(N_1(u-) = j) > 0$, then as $n \rightarrow \infty$,

- (i) $\hat{\gamma} \rightarrow \gamma$ in probability and $\sqrt{n}(\hat{\gamma} - \gamma) \xrightarrow{d} N(0, \Sigma(\tau, \gamma))$, where $\Sigma(\tau, \gamma) = D(\gamma) \Upsilon(\tau, \gamma)^{-1} D(\gamma)$ and

$$\Upsilon(\tau, \gamma) = \int_0^\tau [D(\rho(u; \gamma)) - \rho(u; \gamma) \rho(u; \gamma)'] \gamma' q(u) dR(u),$$

with $D(\eta)$ representing a diagonal matrix with diagonal elements η .

- (ii) Further, if $\gamma' q(\tau) > 0$, then

$$\{\sqrt{n}(\hat{R}(s) - R(s)) : 0 \leq s \leq \tau\}$$

converges weakly to a zero-mean Gaussian process with variance function

$$K(s; \gamma) = \int_0^s [\gamma' q(u)]^{-1} dR(u) + \varrho(s; \gamma)' \times [\Upsilon(\tau; \gamma)]^{-1} \varrho(s; \gamma), \quad (18)$$

where $\varrho(s; \gamma) = \int_0^s \rho(u; \gamma) dR(u)$.

PROBABILISTIC WORK

Here, we summarize some probabilistic results pertaining to load-sharing systems. Daniels [4] showed that the strength of a bundle of parallel fibers is asymptotically normally distributed. It is assumed that when a free load is applied to the bundle all the fibers extend by an equal amount and for each fiber, there is a definite extension and load at which it breaks. Suppose the load on a bundle of n parallel fibers is increased gradually from 0 to its final value, at first it is distributed between the n fibers and equilibrium may be reached without any fiber giving way. However, if the load is great enough, one of the fibers may break and the load is redistributed among the remaining $n - 1$ fibers, each bearing a larger load than before and so being more likely to break. In this manner, a number of fibers may break successively until either a point of equilibrium is reached where the surviving fibers have sufficient strength to carry the final load between them, or no such point is reached and all the n threads ultimately break, in which case, the bundle is broken. The minimum load beyond which all the fibers of a bundle break is called the *strength* of the bundle.

We consider below the situation from Ref. 4 where all fibers have the same load-extension ratio and each fiber bears an equal share of the load. Let the breaking loads or strengths $X_1, \dots, X_n$ of the n fibers of the bundle be i.i.d. random variables with common probability density $f(x)$ and c.d.f. $F(x)$. Let S denote the total load applied to the bundle and let the corresponding load on each of the r out of n surviving fibers at equilibrium be s . It is assumed that r satisfies the relation

$$r = n(1 - F(s)).$$

Since each fiber bears an equal share of the load,

$$S = rs = ns[1 - F(s)],$$

and the (expected) breaking load S_b of the bundle occurs when $s = s_b$ satisfies

$$\frac{d}{ds_b} \{S_b[1 - F(S_b)]\} = 0$$

and gives S its greatest possible value.

Let $X_{(1)}, \dots, X_{(n)}$ denote the ordered strengths of the n fibers. If T denotes the strength of the bundle, then under the equal load-share assumption,

$$B_n(S) = P[T \leq S] = P[nX_{(1)} \leq S, (n-1)X_{(2)} \leq S, \dots, X_{(n)} \leq S].$$

Thus

$$B_n(S) = n! \int_0^{S/n} f(x_1) dx_1 \int_{x_1}^{S/(n-1)} f(x_2) dx_2 \cdots \times \int_{x_{n-2}}^{S/2} f(x_{n-1}) dx_{n-1} \int_{x_{n-1}}^S f(x_n) dx_n.$$

Daniels established that if $s(1 - F(s)) \rightarrow 0$ as $s \rightarrow \infty$, then as $n \rightarrow \infty$, $B_n(S)$ tends to a normal distribution with mean $S_b = ns_b[1 - F(s_b)]$ and variance $s_b^2 n F(s_b)[(1 - F(s_b))]$.

Smith [17] extended his results to a series parallel model (see also **Systems in Series** and **Parallel-Series and Series-Parallel Systems**) consisting of a long chains of bundles put together in series.

Coleman [18] found the mean time to ultimate failure of a bundle of parallel fibers when the number of fibers becomes large. Birnbaum and Saunders [19] derived the life-time distributions of the materials. Phoenix [20] showed that the system failure is asymptotically normally distributed as the number of components become large. All above results are derived for the equal load-sharing model.

Lynch [21] characterized some relationships between the failure rate and the load-share rule. Durham and Lynch [22] showed that when components have independent exponential lifetimes, the system lifetime has a threshold representation of the form $\frac{S}{\theta}$, where S and θ are independent random variables with S being a gamma variable with scale 1 and varying shape parameter, and θ is interpreted as the random environmental stress on the system with a given density.

Harlow *et al.* [23] justified the use of a Weibull distribution for the strength of a single fiber. They also showed that a Weibull distribution with different scale and shape parameters is appropriate for the lower tail distribution of a parallel system subject to some load-sharing rule. They have also considered a recursive formula for computing the system life distribution under monotone load-share rule. But the formula is very complicated when there are a large number of components in the system. A new algorithm for studying the system distribution is given in Ref. 22. This algorithm is based on graphical techniques. It also gives an insight into the effect of the load-sharing rule on the system lifetime.

Schechner [24] considered stochastic characteristics of a system under the linear breakdown rule, that is, the failure rate of a component at any time t is a linear function of the load applied at time t . He showed that if the load rule is nondecreasing, then the failure time has the increasing failure rate (IFR) property. Further, if components have independent exponential lifetimes, then the system lifetime has an asymptotically normal distribution when the number of components is large.

Tierney [25] considered a composite material consisting of a set of stiff parallel fibers embedded in a flexible bonding matrix. The time of composite failure depends on the load applied and the properties of individual fibers. He derived two approximations to the distribution of time to failure under local load sharing. In the first case, the entire distribution is approximated by uniformly small absolute errors. In the second case, the lower tail is approximated by a small relative error. For more probabilistic results under local load sharing see Harlow and Phoenix (1982), Tierney (1982) and Kuo and Phoenix (1987).

A dynamic modeling approach for the reliability of a coherent system, which accommodates the fact that the failure of a set of components may result in a change in the structure function and change the distribution function of the lifetimes of the surviving components, is discussed in Hollander and Pena (1995).

DATA SETS

In this section, we describe some data sets from the literature useful for illustration of load-share models.

Example 1. Data on 50 male and 50 female litters, each of three rats are reported in Ref. 26. One rat in each litter was drug-treated and the other two served as control animals. The records are either on the week of tumor appearance or the week of death. The death of a littermate may affect the lifetime of the surviving animals. If one deletes the litters with tumor deaths and also the litters in which either both the control animals were sacrificed or died at the end of 104 weeks, the time at which the study was either ended or censored, there are 48 male litters and 22 female litters whose exact death times are known. In case of the male litters, a nonparametric test procedure proposed in Ref. 27 does not reject the null hypothesis H_0 that the first death does not affect the second death, whereas in case of the female litters, it rejects H_0 even at 1% level of significance in favor of the alternative that death of a littermate increases the residual life of the surviving mate.

Example 2. McCool [6] has reported data on ball bearings. The data consist of first and second failure times of bearings on a given unit (system) for six such units. Based on his test (LS_1) described above in the section titled "Models And Statistical Inference," he concludes that there was an influence of the first failure on the second failure. The same conclusion is reached in Ref. 27.

Example 3. In Ref. 16, the authors have discussed life testing of plasma display devices (PDPs). PDP degradation is measured in luminosity and failure is declared when luminosity decreases below a given threshold. The measurements are recorded by sensors spaced evenly across the surface of the PDP. The aim was to determine whether sudden pixel failures indicated by one sensor would affect the degradation at other parts of the PDP. The number of sensors can be considered to be equivalent to the number of components. The authors present simulated

data with sample size $n = 20$, number of sensors $k = 3$ and lifetimes for the three sensors for each of the 20 devices. They conclude that there is a slight indication of an increased failure rate after the first observed failure.

Example 4. Data on failure times of ventilating tubes inserted in ears of children with chronic otitis media with effusion (OME) are reported in Ref. 28. Otitis media or inflammation of the middle ear is a common childhood illness, the most common form being OME. The authors carried out a study to determine possible effect of a medical treatment in the prolonging of tube life. Censored survival times of tubes are observed for ears with treatment and ears without the treatment (controls) forming two samples. For comparing the two samples, they propose a test that incorporates the fact that the survival times of tubes in the left and right ears of the same child may not be independent. Failure of the tube in one ear may increase the failure rate of the tube in the other ear. The data consist of censored failure times of tubes in each ear for 41 children with the treatment and 39 without the treatment after placement of the tubes.

Example 5. Reliability Edge Home [29] reports a data set obtained from a life test on 18 parallel systems consisting of two motors operating continuously. For each system, the failure times of both the motors along with their identification labels are given.

CONCLUSIONS AND FUTURE WORK

Herein, we have reviewed the existing literature. The emphasis has been on the statistical models proposed in the literature and associated inference problems. There are several papers available on the probabilistic aspects of load-sharing systems. All related references have been listed for further reading.

The authors along with Deshpande in Ref. 27 have studied a model for k -out-of- m load-share systems that incorporates the changes in the performance of the surviving

components due to the failure of a component in the spirit of dynamic reliability systems. These models, for various choices of the initial distribution function F , give us families of distributions that incorporate load-sharing ideas. We have considered two-component parallel load-share systems and some observations, schemes, and identifiability issues under them. We have constructed a general semiparametric bivariate family of distributions that explicitly models this phenomenon through proportional conditional hazards, and have given estimates for the constant of proportionality. We have proposed a nonparametric test for the hypothesis that the failures take place independently versus first failure affects the failure rates of the surviving components, which may be used with any continuous distribution for the component lifetimes and have obtained estimates of the power of the test, and we observe that it is quite high even for moderately distant alternatives. We are also looking at nonparametric estimation of the hazard rates of the proposed model in the presence of covariates and at other nonparametric test procedures.

LOCATION (HOTELLING) GAMES AND APPLICATIONS

STEFFEN BRENNER
Department of International
Economics and Management,
Copenhagen Business School,
Frederiksberg, Denmark

INTRODUCTION

The location of a production facility or a retail outlet may frequently be an important determinant of economic success, for example, because resources or customers are within easy reach, or because transportation to and from the facility is efficient to organize. Even though most of economic research abstracts from the exact location of economic activities, during the past decades, the analysis of spatial location patterns has become a well-developed research stream transcending into fields of regional economics, industrial organization, and international trade. One of the dominating paradigms of studying spatial competition was provided by Hotelling's [1] pioneering study.

Hotelling's original model contains two firms that plan to set up shop in a street of finite length. His main proposition is that firms agglomerate in the center of the street. Interestingly, pointing out an error in the argument regarding the equilibrium and slightly modifying the model led to the opposite result of extreme differentiation [2]. Also in reality, we observe agglomeration and differentiation. The former occurs, for example, in the form of shopping malls where retail businesses benefit from economies of local concentration. In contrast, differentiation tends to prevail when it comes to supermarkets that typically do not to operate next to each other. Hence, differentiation patterns seem to depend on further determinants upon which we will elaborate in this article.

Competition in Hotelling games is local, that is, firms compete for customers with their direct neighbors along the spatial domain. Commonly, the equilibrium results of Hotelling games are driven by a basic trade-off between two opposite effects of relocation: the positive (short-run) demand effect, which leads firms to locate close to their direct neighbors in order to attract a high demand, and the negative (long-run) price effect, which results from the increased local competition. The relative strength of those effects decides upon which equilibrium pattern is established: either the maximum, the minimum, or an in-between differentiation solution (given an equilibrium solution exists).

Hotelling's model was reviewed and modified many times such that, now, a huge body of literature exists from which we can draw. Reviewing the literature shows that the relative strength of the centripetal and the centrifugal forces in the model depends on a variety of features of the considered market, in particular on how the price competition is set up, demand elasticity, incentives to collocate, distribution of customers, uncertainty, and number of firms and dimensions. Note that the model of spatial competition easily mutates into a model of product differentiation. Instead of interpreting the domain of the model as space, we consider it as a dimension in the product characteristics space. For example, the product ice cream may differ with respect to the fat content. Varieties of ice cream may range from low fat to very fat, and just as a firm may choose an address on the street for its shop, it may choose the exact fat content in its ice cream.

The organization of the survey is as follows. In the section titled "Location Models with a Price Setting Stage", the reference model will be presented. The section titled "Determinants of Differentiation" surveys the literature, providing the reader with a discussion of the determinants of differentiation. The final section concludes the article.

PURE LOCATION GAMES

Most of the models in the spirit of Ref. 1 allow the players to make two choices: the location from which products are sold, and the price these firms charge for them. However, a series of influential papers have abstracted away from the choice of the price, and looked at whether location equilibria exist, and how they can be characterized when the location has no impact on the pricing. In a simple interval model with two firms, under general conditions, one would find that firms choose the same locations in equilibrium. Eaton and Lipsey [3] show that this pattern is not supported anymore when the number of firms is higher than two, and when other restrictive assumptions are abandoned. Eaton and Lipsey [3] furthermore conjecture that no pure Nash equilibrium in locations exists when the number of firms is at least three. Shaked [4] actually shows that such equilibria, indeed, do not exist in the plane if the number of firms equals three. Okabe and Aoyagi [5] analytically show that there is a marked difference in the location patterns if one compares one- and two-dimensional spaces. While under some conditions, one-dimensional domains are associated with a low degree of spatial differentiation, the distance between the players' locations substantially increases in the two-dimensional space.

LOCATION MODELS WITH A PRICE-SETTING STAGE

As mentioned already, one may interpret the model along a spatial or a product characteristics dimension. In order to avoid confusion, we will henceforth stick to the interpretation on the domain of product differentiation. There are n firms producing a good at zero marginal cost. The products are horizontally differentiated. We consider a domain of product characteristics, which is projected onto the unit interval, that is, each value from the $[0, 1]$ -interval represents a realization of an ordered set of product characteristics. In some cases we allow for a unit circumference representation. There is an infinite number of

customers i whose preferences for the product characteristics w_i are distributed along the unit interval with distribution $F(w_i)$.

The model is a two-stage game of complete information. In the first stage, firms $i = 1, \dots, n$ choose product characteristics $\bar{x} = (x_1, x_2, \dots, x_n) \in [0, 1]^n$ simultaneously before posting prices $\bar{p} = (p_1, p_2, \dots, p_n) \in R^n$ in the second stage of the game. This reflects the idea that producing a product requires a long-term commitment while setting the price can be done instantaneously. Without loss of generality, we assume $0 \leq x_1 \leq \dots \leq x_n \leq 1$. Finally, customers decide whether to buy and if so which product to buy. This decision is determined by the preference w_i of the customer, the available products, and their respective prices according to the following indirect utility function

$$u(k_j, w_j, p_i, x_i) = k_j - p_i - d(x_i - w_j),$$

where p_i is the price charged for the product of firm i , $d()$ represents any distance function, which is monotonously increasing. This function measures the disutility, which is related to the difference between the amount of the characteristics of the most preferred product w_j and the considered product x_j . These disutility costs are referred to as *transport costs* in this article. An outside option is accounted for by reservation price $k_j > 0.5$. We assume that the number assigned to a firm corresponds to its rank in the spatial ordering, that is, firm 1 is at the extreme left and firm n is at the extreme right. We focus on Nash equilibria as the only equilibrium concept.

Let us derive the equilibria in the simple case when the number of firms is two and transport costs are quadratic. That is, $d()$ is a quadratic function [2]. We first establish the equilibrium of the second stage of the game where prices are chosen. One typically starts by computing the demand for each firm by determining the location $\hat{w}$ of the customer who is indifferent to buying from either firm. Specifically, from $u(k, \hat{w}, p_1, x_1) = u(k, \hat{w}, p_2, x_2)$ we obtain

$$p_1 + (x_1 - \hat{w})^2 = p_2 + (x_2 - \hat{w})^2,$$

and after some transformations, $\hat{w} = \frac{p_2 - p_1}{2(x_2 - x_1)} + \frac{x_1 + x_2}{2}$ yields. All the demand

located to the left of $\hat{w}$ is served by firm 1, and the remaining demand is served by firm 2. To be more exact, since $\hat{w}$ may lie outside the unit interval, the demand for firm 1 is equal to $D_1 = \max\{0, \min\{\hat{w}, 1\}\}$. For simplicity, we assume that $\hat{w}$ is inside the interval's boundaries. Taking the first derivative of the profit functions of both firms with respect to the firm's own price and solving for it yields the following price-response functions:

$$p_1(p_2) = \frac{p_2 + (x_2 - x_1)(x_1 + x_2)}{2}$$

$$p_2(p_1) = \frac{p_1 + (x_2 - x_1)(2 - x_1 - x_2)}{2}$$

From these two equations, we can easily infer the prices in equilibrium by inserting one expression into the other one.

$$p_1^* = \frac{(x_2 - x_1)(2 + x_1 + x_2)}{3}$$

$$p_2^* = \frac{(x_2 - x_1)(4 - x_1 - x_2)}{3}.$$

Having solved the second stage of the game, we may now turn to the first stage. Anticipating the price setting behavior just derived, we are now ready to compute the best response function regarding locations by computing the first-order condition on profits $\pi_1(x_1, x_2)$ as follows:

$$\begin{aligned} & \frac{\partial \pi_1(x_1, x_2)}{\partial x_1} \\ &= \frac{\partial [p_1^*(x_1, x_2) \hat{w}(x_1, x_2, p_1^*(x_1, x_2), p_2^*(x_1, x_2))]}{\partial x_1}, \\ & \frac{\partial \pi_2(x_1, x_2)}{\partial x_2} \\ &= \frac{\partial [p_2^*(x_1, x_2)(1 - \hat{w}(x_1, x_2, p_1^*(x_1, x_2), p_2^*(x_1, x_2)))]}{\partial x_2}. \end{aligned}$$

With $\hat{w}(x_1, x_2, p_1^*(x_1, x_2), p_2^*(x_1, x_2)) = \frac{2+x_1+x_2}{6}$, we obtain

$$\frac{\partial \pi_1(x_1, x_2)}{\partial x_1} = -\frac{(2 + 3x_1 - x_2)(2 + x_1 + x_2)}{18},$$

$$\frac{\partial \pi_2(x_1, x_2)}{\partial x_2} = \frac{(4 + x_1 - 3x_2)(4 - x_1 - x_2)}{18}.$$

It is easy to see that the first derivative is negative for firm 1 and positive for firm 2, provided that $x_i \in [0, 1]$. Hence, irrespective of the location of the other player, firm 1 would always benefit from moving to the left, and firm two would benefit from moving to the right. As a result, $x_1^* = 0$ and $x_2^* = 1$. At the equilibrium prices, we obtain $p_1^* = p_2^* = 1$.

DETERMINANTS OF DIFFERENTIATION

As we will see below, the considered models allow for a great variety of equilibrium outcomes in prices and locations, which range from minimum to maximum differentiation, and from soft to tough price competition. We show how differentiation is affected by a variety of parameters of the market structure game. We start with the determinants of price competition. Note that for a subset of model parameters, the games are plagued with the nonexistence of equilibria.

Price Competition

The competition in prices is affected by two model features: the transportation costs and the general pricing strategy of the firms. Let us first concentrate on the impact of transportation costs on price competition. The specific way as to how these costs are modeled plays a central role in research on product differentiation. Furthermore, existence of price equilibrium and thus the existence of subgame perfect equilibrium for the whole game depend on transport costs. Transport costs influence the price competition between two firms by the number of customers, which a firm is able to withdraw from (lose to) its neighbor by decreasing (increasing) its price by one unit. We refer to this concept as the *degree of price competition*. More formally, we use the first derivative of the demand function with respect to the price as a measure for the degree of price competition.

Table 1 lists the papers on duopoly Hotelling models with uniformly distributed customers and inelastic demand across different specification of the transport costs. The first five articles are devoted to the interval model and the last two papers consider the circumference domain. The

Table 1. Studies on Horizontal Product Differentiation and Transport Costs

Article	Domain	Cost Function	Existence of Price Equilibrium	Equilibrium Locations	Degree of Price Competition
Hotelling [1]	Interval	$d(x) = ax$ $a > 0$	No	—	$\frac{1}{2a}$
d'Aspremont <i>et al.</i> [2]	Interval	$d(x) = bx^2$	Yes	Maximum differentiation	$\frac{1}{2bx}$
Economides [6]	Interval	$d(x) = bx^\alpha$ $b > 0$ $1 \leq \alpha \leq 2$	If $1.26 < \alpha < \frac{5}{3}$ If $\frac{5}{3} < \alpha \leq 2$ Not otherwise	Interior Maximum differentiation —	$\frac{1}{ab(y_1^{\alpha-1} + y_2^{\alpha-1})}$ where $y_i =$ $ D_1(p) - x_i $
Gabszewicz and Thisse [7], Anderson [8]	Interval	$d(x) =$ $ax + bx^2$	No	—	$\frac{1}{2a+2bx}$
Katz [9]	Circular	$d(x) = ax$ $a > 0$	No	—	$\frac{1}{a}$
de Frutos <i>et al.</i> [10]	Circular	$d(x) = ax +$ $bx^2, a \geq 0$ $b \in \mathbb{R}$	If $a = 0$ or if $a = -b$ Not otherwise	Maximum differentiation Maximum differentiation —	$\frac{1}{a+bx}$

fourth column indicates whether a price equilibrium exists for this class of cost functions. In the class of interval models, an equilibrium on the price setting stage only exists for quadratic and a subset of convex nonlinear cost functions considered by Economides [6]. However, convexity is not sufficient to ensure the existence of the price equilibrium (see fifth and sixth row). Rather, it is the non-quasi-concavity of the profit function that prevents the equilibrium existence. One may suspect that the degree of price competition is related to the existence of a price equilibrium. Both cases, which provide the existence of an equilibrium, are associated with an infinitely high degree of price competition if firms are very close (see last column of Table 1). In contrast, in the setup examined by Gabszewicz and Thisse [7] and Anderson [8] price competition has an upper bound even if firms locate at the same position. However, as proved by Anderson [8], configurations in which firms are located very closely and in which firms are located

very distant imply an equilibrium. For a region in-between, the equilibrium breaks down. Hence, there is no clear relationship between the degree of price competition and the existence of a price equilibrium for the interval model.

Unfortunately, previous analysis is restricted to rather simple functional forms of the transport costs. Although it would be desirable to have some theorems on the conditions of nonexistence of the price equilibrium, establishing them represents a hopeless task ([7], p. 167). Thus, for a great variety of transport functions no price equilibrium and hence, no subgame perfect equilibrium exist.

Furthermore, the degree of price competition is not linked to the existence of price equilibria via a simple relationship. In the circumference model, the price equilibrium does not exist in the case of linear transport costs [9] but exists if costs are linear quadratic [10]. Hence, both convex and concave functions may allow price equilibria.

Concentrating on the cases where equilibrium existence is of no concern, we see that the degree of price competition and the pattern of differentiation are related in the way intuitively expected [6]. Hence, given that a price equilibrium exists for the duopoly Hotelling model with uniformly distributed consumer preferences on the unit interval, then the higher the degree of price competition the stronger is the strategic differentiation. It is worth mentioning that differentiation does not range from minimum to maximum differentiation but rather from in-between to maximum differentiation. From this result, minimum differentiation does not seem to be a likely outcome. We will see below that minimum differentiation can still be obtained by relaxing other model parameters. For the circular model, de Frutos *et al.* [10] show that the principle of maximum differentiation is dominating because firms would always like to differentiate unless linear transport costs are assumed. In the previously mentioned papers, transport costs were taken to be exogenous. However, several examples like PCs designed to fulfill a wide range of functions or cosmetic products (“all in one”) suggest that firms try to reduce the disutility to consumers incurred by the distance of their preferred good and the offered good measured in the space of product characteristics. von Ungern-Sternberg [11] and Hendel and de Figueiredo [12] tackle this problem for the circular domain. In their model, firms first choose to enter and then choose a location. Subsequently, they set transport costs and prices simultaneously [11] or sequentially [12]. If the transport costs are close to zero, the general-purpose of the product is said to be high. Otherwise, the product design is said to be focused. Transport costs are assumed to be linear with a variable slope parameter. In the simultaneous choice model, firms set transport costs at a rather low level (lower than socially optimal), which increases price competition. In the sequential setup of Ref. 12, however, the choice of the focus introduces a strategic effect on pricing. The impact strategic focusing has on price competition is not straightforward. In the duopoly case where changing the focus is

costless, firms have an incentive to increase their focus in order to relax price competition. For the case $n > 2$ this relation does not hold anymore. Here firms are interacting with two different neighbors, resulting in externalities of any change in prices. Consequently, firms increase the general purpose of their products and set prices at marginal costs. Given that entry only occurs at fixed cost there is no equilibrium with more than two firms. Hence, despite free entry, in equilibrium there are only two firms in the market. However, if changing the focus is associated with costs the results change for $n > 2$. In this case, the focus will be increased by the firms leading to positive prices and hence, possible oligopoly equilibria.

A final note is due regarding the plausibility of different functional forms of transport costs. Lancaster ([13], Chapter 2) argues that in contrast to quadratic costs, linear transport costs are inconsistent with plausibly shaped indifference curves.

Pricing Strategies

The lion’s share of papers on Hotelling models assumes mill pricing, that is, firms sell the products at an fob (free on board) price, which is not related to the location of the consumers. Another possibility would be to charge spatially discriminatory prices. Here, for example, firms charge lower prices from customers who are more distant. Applied to the domain of product differentiation there exist two possible interpretations. The obvious one is that firms compensate the disutility customers incur from buying a product whose characteristics are not aligned to their preferences by adjusting the price accordingly. That is, firms would charge different prices depending on the location of customers in the characteristics space. Another interpretation is that firms redesign the goods to be sold (which is assumed to be done at zero cost), pay the cost of transport, and charge a uniform total price. Both price strategies can be observed in reality: discriminatory and nondiscriminatory price-setting. An industry where the two forms occur simultaneously is the book retail industry. Books may be either bought in the book shop or by

one of the numerous mail-order or internet book retailers at a similar compound price (including transportation).

The impact of different price regimes on spatial competition was considered in Refs 14–19. From the competition point of view, the impact of the choice between mill pricing and discriminatory pricing is not straightforward. First, the opportunity to discriminate on prices increases the firm's flexibility. A number of articles show the profit enhancing effect of monopolistic price discrimination [20]. However, in the short-run, firms would prefer mill pricing. This is because mill pricing offers the opportunity to commit to a set of prices while in discriminatory pricing it is possible to cut prices at each location separately. Gabszewicz and Thisse [21] point out that under discriminatory pricing, there is a separate Bertrand price game at each location of the interval. Hence, price competition is tougher under discriminatory pricing resulting in lower equilibrium prices [16]. Moreover, it was shown for a general set of conditions that if prices and price regimes are chosen simultaneously, discrimination occurs as an equilibrium. Additionally, under more rigid assumptions the sequential subgame of first choosing the price regime and then posting a price simultaneously delivers the same result [16].

Tabuchi [18] analyzes the case in which marginal costs of production differ between discriminatory and mill pricing. Mill pricing yields as an equilibrium only if marginal costs of discriminatory pricing are much larger than marginal costs of mill pricing. However, taking into account the long-run effect of discriminatory pricing on entry, fewer firms enter the market. The higher concentration of firms is accompanied by higher profits [17]. Consequently, discriminatory pricing can be applied as an effective deterrent of entry. However, if entry is blockaded exogenously, incumbent firms would generate greater profits using mill pricing.

Zhang [19] examines the effect of price-matching policies on the Hotelling game. If a firm follows a price-matching policy, it is committed to match or beat the prices of its competitors. The game has three stages:

(i) location choice, (ii) decision about the price-matching policy, and (iii) setting the price. Here again, an instrument that seems very competitive leads to a softer price competition via the strategic effect of entry deterrence. Consequently, even though we assume quadratic transport costs, in equilibrium, the locations follow the minimum differentiation principle.

Elasticity of Demand

The standard Hotelling model makes the rather unrealistic assumption that demand is inelastic. Relaxing this assumption may have two effects. First, equilibrium prices can be expected to decrease if demand elasticity is sufficiently high because then it is worthwhile for the firms to attract new demand by decreasing their prices. Second, price competition between the firms may be cooled because the firms' focus will become increasingly local. Since transport costs are paid by the customers, the real prices are lower for customers close to the firm, who are easily attracted even if demand elasticity is high. Consequently, this would lower the incentives to differentiate to the maximum.

Several papers contribute to model generalizations in this respect. Smithies ([22], p. 432) investigated a setting in which the consumers are individually endowed with a linear inverse demand function. He argued informally that firms would locate "closer to the center than to the quartiles." Customers in the hinterland of each firm are not necessarily attracted by the respective firms if demand is elastic. Salop [23] concentrates on the price stage given symmetric locations of firms on the circumference and shows the existence of the price equilibrium if there is an outside good. Böckem [24] models a continuum of consumers whose reservation price $k \in [0, 1]$ is distributed uniformly over the interval. Assuming a duopoly with quadratic transport costs she showed that a price equilibrium exists, and further that firms locate between maximum and minimum differentiation. The numeric solution of equilibrium locations is $[0.272, 0.728]$. Indeed, it is the effect that it pays for the firms to be close to the demand, which attracts them toward the market center.

Hinloopen and Marrewijk [25] elaborate on a similar setup where transport costs are linear and the reservation price is constant across consumers. Given that the reservation price is sufficiently high, the original Hotelling result holds in which no price equilibrium exists. If the reservation price is low, firms become local monopolists, and a continuum of equilibrium locations yield including maximum and intermediate differentiation. However, reservation prices in-between imply symmetric equilibrium locations where the distance between the firms is between one-fourth and half of the market. For a range of reservation prices there exists a negative relationship between this value and the amount of differentiation. Hence, given a price equilibrium exists for the duopoly Hotelling model with uniformly distributed consumer preferences on the unit interval then the higher the elasticity of demand the less firms will differentiate.

Collusion

The games usually considered in spatial competition assume noncooperative behavior of firms. However, through frequent interaction firms might partially build up a cooperative attitude toward their competitors resulting in collusive agreements. Firms may collude on both locations and prices. In the duopoly examined by d'Aspremont *et al.* [2] this would lead to profit maximizing (and socially optimal) locations at the quartiles. Jehiel [26] and Friedman and Thisse [27], however, argue that firms will likely collude on prices only since locations are fixed once for all. Following the collusive agreement implies bearing the risk of being cheated. If a rival deviates from the collusive outcome, revenge could be taken only via prices, which may not be credible. For the case that firms are allowed to collude only in prices, Jehiel [26] and Friedman and Thisse [27] consider a game of location choice in the first stage followed by an infinitely repeated price game. While Jehiel applies Nash bargaining within the cartel, Friedman and Thisse use a profit-sharing rule corresponding to the respective ratio of profits without collusion to determine the

collusive outcome. Without money transfers between competitors, both firms locate at the market center. This result is to be expected since through collusion, the threat of fierce price competition preventing the firms to approach each other disappears. Moreover, taking the same position has the advantage that the threat of cutting the price has the greatest effect on the rivals' profits and thus, making it more probable for collusion to sustain.

The Number of Firms

Let us now address the question of how a firm's choices of location and price is affected by the number of firms. In general, the analytical tractability of Hotelling models decreases with the number of firms. Hence, there is only a limited number of contributions to the multiple firms model. Examining the model on the circular domain, Salop [23] proves the existence of the price stage equilibrium given an equidistant location setting. However, an equilibrium does not exist for every feasible subgame. Again, as in the duopoly, this problem can be circumvented by assuming quadratic transport cost. This assures the existence of a price equilibrium in every subgame and further, the equilibrium existence of the whole game [28]. The locations in this equilibrium can be interpreted as following the principle of maximum differentiation. That is, firms locate equidistantly in order to maximize the minimum distance to their direct neighbors. Hence, in the circular domain, the number of firms does not have a significant effect on the relative amount of differentiation.

In the linear market, the nonexistence of a price equilibrium of Hotelling's original model could be remedied by allowing more than two firms to enter [28]. However, as there are strong incentives for the firms to agglomerate at the market center, a location equilibrium could not be established. Agglomeration is not stable since it is associated with Bertrand competition and deviating increases profits. In (nonequilibrium) equidistant configurations the corner firms are provided with some kind of market power, which enables them to charge

higher prices than their competitors. This is attributable to the fact that corner firms only have rivals on one side and hence, price competition is lower than for inside firms. The price structure is U-shaped, that is, prices decrease toward the center firms.

A similar setup with quadratic transport costs was analyzed by Brenner [29]. He shows that a price equilibrium exists for every feasible subgame and further, that the principle of maximum differentiation does not carry over to the multiple firms case. For games with up to nine players, equilibria are calculated, which are characterized by a U-shaped price structure. Moreover, corner firms locate inside the interval, which manifests their market power. However, if more than three firms are in the market, the equilibrium differentiation pattern does not much deviate from the socially optimal pattern.

In summary, allowing more than two firms to compete has the following effects. The price competition is not endangered although it seems to be softened. This effect arises because there exists an externality of a price change. By responding to an action of one neighbor, a firm also has to take into account the response of the second neighbor. Consequently, the maximum differentiation equilibrium in the linear market with quadratic transport costs is destroyed. Furthermore, given a market boundary the corner firms enjoy a market power from possessing a hinterland, which is reflected in higher prices and higher profits than their competitors if $n > 3$.

Customer Distributions

In the standard model, customers are distributed uniformly over the unit interval or the circumference. However, in the domain of product characteristics one usually finds customers' preferences clustered around some brands while in a geographic space, there is often an agglomeration of inhabitants at the business center of a town. Intuitively, we might expect that differentiation decreases as the density at the interval center increases, while price competition gets fiercer. In the

extreme case where all the density is concentrated in one point, the Bertrand paradigm results.

Several attempts have been made to relax the uniform distribution assumption. Shilony [30] has proven that the problem of equilibrium nonexistence in Hotelling's original model could not be solved by allowing more general density functions. Interestingly, the locations that provide price equilibria still imply a tendency to agglomerate. Assuming quadratic transport costs, Neven [31] has shown that for concave symmetric distributions a price equilibrium exists and further, that the whole game has an equilibrium. For distributions that are not too concave maximum differentiation holds. From a certain degree of concavity onward, however, firms choose inside locations, which are not more than one-eighth away from the interval boundaries.

In their frequently cited paper, Caplin and Nalebuff [32] have demonstrated that price equilibria exist for the broader class of log-concave distributions. This finding has led to the question of whether equilibrium existence holds for the whole game. Tabuchi and Thisse [33] found that symmetric locational equilibria do not exist for the subclass of triangular density functions. It was suspected that the nondifferentiability of the density at the median point would be the reason for this.

The most general approach to this problem so far was presented by Anderson *et al.* [34]. Considering a setup of quadratic transport costs and unrestricted locations on the real line, they have shown for the class of log-concave distributions that symmetric location equilibria exist only if the distribution of consumers is not too concave at the center. Otherwise, asymmetric equilibria may appear given the distribution not being too asymmetric. By positioning asymmetrically, firms shift the marginal consumer away from the very competitive region of high density to a more remote area in order to relax the competition.

Uncertainty

Uncertainty by the firms about an auxiliary dimension of product characteristics was

introduced by Rhee *et al.* [35]. In their model of linear transport costs, a variety of possible outcomes exist. If consumers exhibit sufficient heterogeneity along the unobservable attribute, minimum differentiation results. In contrast, the level of differentiation increases along the observable attribute as the uncertainty about the other dimension decreases. Moreover, increased uncertainty makes the competition more and more irrelevant leading to increasing prices.

Multiple Dimensions

Adding further spatial dimensions may influence the outcome of the game [36,37]. Neven and Thisse [36] demonstrate that maximum differentiation prevails at one dimension while agglomeration is observed at the other. Along which dimension the distance is maximized depends on the relative length of those domains. For the case of a two-dimensional plane of horizontal product differentiation (a square) minimum differentiation results along one and maximum differentiation along the other dimension.

This finding gives rise to the question of whether introducing further dimensions along which firms are able to differentiate from rivals leads to more or less differentiation. Irmen and Thisse [38] show that along all but one dimension firms agglomerate. Dimensions are weighted differently according to their relative importance. The dimension which is weighted maximally is used to differentiate. Even for the three-firms case it could be shown that maximum differentiation is never an equilibrium.

CONCLUSIONS

This survey reveals that differentiation—either in geographic or product space—depends delicately on parameters of the market structure. With respect to the degree of price competition, the existing literature suggests that it becomes tougher

- as discriminatory pricing or price-matching is available as a strategy,
- as the demand elasticity becomes lower,
- when fewer firms are competing,
- when the density of consumers is less concentrated in the center of the market,
- as the firm's uncertainty increases regarding the heterogeneity of consumers' preferences of a second dimension of product characteristics,
- if advertising tools are available that shift consumers toward the advertised product.

Furthermore, price competition is eliminated if firms are able to collude in prices. If the number of dimensions increases, price competition seems to become more and more irrelevant since differentiation occurs only along one single dimension. Endogenous transport costs, however, are inconclusive with respect to price competition. The degree of price competition affects the location choices via the strategic effect. If price competition becomes tougher, differentiation is fostered, and vice versa. Furthermore, there are effects of the model parameters, which directly influence profits of the location choice. In particular, differentiation is increased if the density of customers becomes more concentrated. Furthermore, there is a tendency to agglomerate when collusion is permitted in order to punish a deviating rival maximally.

One of the points of concern about the Hotelling literature is the strong imbalance between the number of theoretical papers on the one side and the number of empirical and experimental papers on the other. Notable exceptions are the empirical studies in Refs 39–41. The former two estimate a highly localized discrete-choice model in a space of several dimensions of product characteristics. The latter discriminate between theories of localized and global competition. Simplified versions of the Hotelling game were subject to experimental research. The impact of collusion in the location choice stage was examined by Brown-Kruse *et al.* [42] and Brown-Kruse and Schenk [43]. In laboratory experiments, individuals have chosen

- as the transport costs become more convex,

to locate at the center if communication was possible. Otherwise, there was a tendency toward the profit maximizing point at the quartiles. Huck *et al.* [44] investigated how individuals behave in a four-players game without price competition. In the Nash equilibrium, two players locate at each of the quartiles. The experimental results, however, suggest that because of best-response dynamics there is a tendency to locate at the center of the market.

LOT-SIZING

WILCO VAN DEN HEUVEL
Econometric Institute, Erasmus
University Rotterdam,
Rotterdam, The Netherlands

INTRODUCTION

Lot-sizing is one of the key planning activities involved in production and inventory management. Every firm that faces customer demand needs to decide when to produce (or order) and in what quantities, in order to satisfy the demand. Typically, firms incur fixed costs for every time production takes place, and holding costs for carrying items from a period to the next period. In general, if production takes place frequently, average fixed costs are relatively high, while holding costs are relatively low. On the other hand, in the case of infrequent production and higher production quantities, average fixed costs are relatively low, while holding costs are relatively high. The objective of a lot-sizing model is to determine an optimal production plan, that is, the timing and level of production such that demand is satisfied and costs are minimized.

The term *lot-sizing* is usually used in the case of deterministic demand in the literature. The economic order quantity (EOQ) model is probably the most famous lot-sizing model in production and inventory management [1]. In this infinite and continuous-time model, we are faced with a constant demand rate that has to be satisfied by placing orders. For every order placed, there is a fixed order cost, while holding costs are incurred for keeping items in stock. The objective is to find the order plan that minimizes the sum of these costs.

This article mainly focuses on the discrete counterpart of the EOQ model: the dynamic lot-sizing (DLS) or the economic lot-sizing model. Both names are used in the literature and can be traced back from the titles of

the two seminal papers “Dynamic version of the economic lot size model” [2] and “Programming of economic lot sizes” [3]. The former paper proposes a polynomial-time solution approach, while the latter paper provides a mathematical formulation for the problem with multiple items. In this article, we use the name *dynamic lot-sizing (DLS)* model as is used most in the literature (based on the number of hits on Google Scholar).

In contrast to the EOQ model, the DLS model has a discrete and finite time horizon. Moreover, “dynamic” refers to the dynamic nature of the demands, that is, the demand quantities may vary over time but they are deterministic (known in advance). The DLS model can be applied both in a production and in an ordering setting. In the first case, demands are satisfied by production, while in the latter case, demands are satisfied by ordering items from an external supplier. We use the term *procurement* to cover both settings.

The remainder of this article is organized as follows. We start the next section with a brief description of the different cost components in lot-sizing models. In the section titled “Continuous-Time Models,” we consider two continuous-time lot-sizing models: the EOQ model and the joint replenishment problem. The following sections deal with the DLS model. In the section titled “The Dynamic Lot-Sizing Model: Formulations,” we present a basic mathematical formulation and discuss two alternative formulations; in the section titled “Solution Methods for the DLS Model,” we give the solution approach proposed in Ref. 2; and in the section titled “Extensions of the DLS Model,” we provide a list of possible extensions of the DLS model. We end the article with some concluding remarks.

COST COMPONENTS IN LOT-SIZING

As already mentioned, a lot-sizing model tries to find a procurement plan that minimizes the total cost. The costs in

lot-sizing models typically consist of the following cost components: fixed procurement cost, unit variable procurement cost, and unit holding cost. In the case of the DLS model, all cost components are allowed to vary over the time periods.

The fixed costs in lot-sizing models do not depend on the procured quantity. In an ordering setting, the fixed cost may consist of the administrative cost, such as typing of orders, receiving orders, handling invoices, and so on. In a production setting, the cost may consist of the labor cost of a mechanic to setup or to change the settings of a machine.

Furthermore, in an ordering setting, the unit variable procurement costs involve the unit purchasing cost, with possibly the addition of freight and handling cost. For producers, the unit production cost consists of the amount of money spent on producing a single item. For example, this includes the cost of the required raw materials and the labor cost to assemble an item. As for the fixed cost, it is assumed that the unit variable costs do not depend on the procurement quantity. For example, this means that we do not consider quantity discounts in the basic models.

Finally, the unit holding costs consist of the cost to keep an item in stock. This includes the cost of running the warehouse, handling items, damage, insurance, and so on. However, the largest portion of the holding cost often consists of the opportunity cost of the capital invested in the inventory. Instead of investing the money in the purchased or produced items, a company could have earned an alternative return on the investment.

It should be clear from the above discussion that, in practice, the precise figures for the different cost components are difficult to calculate or estimate in general. One reason is that they often do not appear explicitly in the accounting systems of most organizations. For a more detailed discussion on the different cost components, we refer to (4, Section 3.6.1).

CONTINUOUS-TIME MODELS

In this section, we consider two continuous-time lot-sizing models. The first model deals

with a single-item problem, while the second model deals with the procurement of multiple items.

Economic Order Quantity Model

The EOQ model dates back to 1913 [1]. In this model, there is a continuous demand rate over an infinite planning horizon. The demand needs to be satisfied by placing orders. For each order placed, there is a fixed order cost and holding cost is incurred for keeping items in stock. To formulate the EOQ model, we use the following notation:

- D : demand rate (in items per unit time);
- K : fixed order cost (in \$ per order);
- h : holding cost (in \$ per item per unit time).

We now determine the average cost per unit time if the order quantity is equal to Q . This means that the time between orders, or the cycle time, is $T = Q/D$ time units and hence the average order cost is $K/T = KD/Q$ per unit time. Furthermore, the inventory is equal to Q items just after the replenishment and there are no items in stock just before the next replenishment. The inventory level over time is depicted in Fig. 1. Thus, the average inventory equals $\frac{1}{2}Q$ with average holding cost $\frac{1}{2}hQ$. So the average total cost per unit time is equal to

$$KD/Q + \frac{1}{2}hQ. \quad (1)$$

Since Equation (1) is a convex function in Q , it is sufficient to use the first-order condition to find the minimum. It follows that the optimal order quantity Q^* is equal to

$$Q^* = \sqrt{\frac{2KD}{h}}$$

and so the optimal cycle time T^* equals $T^* = Q^*/D = \sqrt{2K/(Dh)}$. The total cost in an optimal solution equals $\sqrt{2KDh}$. The optimal order quantity satisfies the property that $KD/Q^* = \frac{1}{2}hQ^* = \sqrt{\frac{1}{2}KDh}$, which means that the average order cost and average holding cost are perfectly balanced in an optimal solution.

Figure 1. Inventory level in the EOQ model.

We note that variable order cost does not affect an optimal solution and hence need not be taken into account in the EOQ model: if the unit variable order cost equals p , then the variable procurement cost equals pQ per order and hence $pQ/T = pD$ per unit time. Since this is just a constant, it does not affect the value of Q that minimizes Equation (1). Finally, because the total cost curve is relatively flat in the area of the optimal order quantity, the EOQ model is a robust model. So as long as the parameter estimates are good (but not perfect), the cost will be very close to the minimum total cost.

Joint Replenishment Problem

Instead of a single item, a firm often needs to determine a procurement plan for a collection of items. Economies of scale occur if several items are procured at the same time. This generalization of the EOQ model is called the *joint replenishment problem (JRP)*. Assume that we have a JRP for n items. There is a fixed cost K_i if item i is ordered and a fixed cost K_0 if any item is procured. Furthermore, we apply the same notation as in the previous section with an additional index i that corresponds to item $i = 1, \dots, n$. Clearly, we save on the fixed cost K_0 if two or more items are procured simultaneously.

In contrast to the EOQ model, the optimal order quantity for an item i does not have to be equal at every replenishment point in the JRP [5]. However, to simplify the problem, many authors apply a policy with equal cycle times and hence equal order quantities for every item. Let T be the base cycle time and let $m_i T$ ($m_i \in \mathbb{N}$) be the cycle time of item

i . So at every m_i th multiple of T , item i is procured. To find the optimal base cycle time T and the multipliers m_i , we need to solve the model

$$\begin{aligned} \min \quad & K_0/T + \sum_{i=1}^n \left(\frac{K_i}{m_i T} + \frac{1}{2} h_i m_i T D_i \right) \\ \text{s.t.} \quad & T > 0 \\ & m_i \in \mathbb{N} \quad i = 1, \dots, n. \end{aligned}$$

Using calculus, it is easy to find the optimal T for given values m_i and conversely, it is easy to find the values m_i for a given T . However, it is not easy to find the optimal T and m_i simultaneously. In fact, it is shown in Ref. 6 that the JRP is $\mathcal{NP}$ -hard. A lot of research has been done to find optimal or near-optimal solutions for the above model. For a review on solution approaches, we refer to Refs 7 and 8.

THE DYNAMIC LOT-SIZING MODEL: FORMULATIONS

In contrast to continuous-time models, the DLS model has a finite and discrete-time horizon. Assume that the model horizon consists of T time periods. We use the following notation for the parameters in periods $t = 1, \dots, T$:

- d_t : demand in period t ,
- K_t : fixed procurement cost in period t ;
- p_t : unit variable procurement cost in period t ;
- h_t : unit holding cost in period t .

It is assumed that all costs are nonnegative. Furthermore, we let $d_{s,t} = \sum_{i=s}^t d_i$ denote the cumulative demand from period s up to period t with $1 \leq s \leq t \leq T$.

In the next section, we give a basic formulation of the DLS model. In the sections titled “The Network or the Shortest Path Formulation” and “The Facility Location Formulation,” we discuss two alternative mathematical formulations that are frequently used in the literature: the network or the shortest path (SP) formulation and the facility location formulation. The advantage of these formulations over the basic formulation is that they are tight. That is, the solution of the linear programming (LP) relaxation is integer. When solving extensions of the DLS model, such as the problem with multiple items and capacity constraints (see the section titled “Extensions of the DLS Model”), the alternative formulations are useful because they often provide better lower bounds.

Basic Mathematical Formulation

In the basic formulation, we use the following decision variables for periods $t = 1, \dots, T$

- x_t : procurement quantity in period t ;
- y_t : is 1 if period t is a procurement period and 0 otherwise;
- I_t : ending inventory in period t .

Then the DLS model can be formulated as the mixed integer programming (MIP) model

$$\begin{aligned} \min \quad & \sum_{t=1}^T (K_t y_t + p_t x_t + h_t I_t) \\ \text{s.t.} \quad & I_{t-1} + x_t = d_t + I_t \quad t = 1, \dots, T \end{aligned}$$

$$\begin{aligned} x_t &\leq d_t y_t & t = 1, \dots, T \\ x_t, I_t &\geq 0 & t = 1, \dots, T \\ y_t &\in \{0, 1\} & t = 1, \dots, T \\ I_0 &= 0. \end{aligned}$$

The first set of constraints are the inventory balance or demand constraints. Demand is satisfied from procurement or inventory from the previous period, while remaining items build up the current inventory. The second set of constraints are the setup forcing constraints, which, together with the fourth set of constraints, ensure that the setup variable is forced to 1 if the procurement quantity is positive. Or alternatively, if there is no setup ($y_t = 0$), then there will not be procurement. Note that the procurement quantity will never exceed the demand from period t to the final period T ($d_{t,T}$), as costs are assumed to be nonnegative. The third set of constraints makes sure that the procurement quantity and inventory are nonnegative. Finally, we assume that the starting inventory is equal to zero.

In fact, the model can be represented as the minimum cost flow network (see also **Minimum Cost Flows**) depicted in Fig. 2. There is one source node 0 with procurement arcs $(0, t)$ to every period t . Furthermore, there is an arc $(t, t+1)$ that carries inventory from period t to $t+1$.

The Network or the Shortest Path Formulation

The network or the shortest path (SP) formulation [9] utilizes the fact that there exists an optimal solution satisfying the zero-inventory ordering (ZIO) property (see the

Figure 2. The DLS problem represented as a network flow problem.

Figure 3. The DLS problem represented as a shortest path problem.

section titled “Solution Methods for the DLS Model” for more details). Such a solution has the property that in a procurement period τ , demands $d_{\tau,t}$ are procured for some $t \geq \tau$. In the formulation, the binary variable $z_{\tau,t}$ is equal to 1 if period τ exactly satisfies the demands for periods $\tau, \dots, t$. The associated variable procurement and holding costs are equal to

$$C_{s,t} = p_s d_{s,t} + \sum_{\tau=s}^{t-1} h_{\tau} d_{\tau+1,t}.$$

Again using the setup variables y_t , the SP formulation is given by

$$\begin{aligned} \min \quad & \sum_{\tau=1}^T (K_{\tau} y_{\tau} + \sum_{t=\tau}^T C_{\tau,t} z_{\tau,t}) \\ \text{s.t.} \quad & \sum_{t=1, \dots, T} z_{1,t} = 1, \\ & \sum_{\tau=1}^t z_{\tau,t} = \sum_{\tau=t+1}^T z_{\tau+1,\tau} \quad t = 1, \dots, T-1 \\ & \sum_{t=\tau}^T z_{\tau,t} \leq y_{\tau} \quad \tau = 1, \dots, T \\ & y_{\tau}, z_{\tau,t} \in \{0, 1\} \quad \tau = 1, \dots, T; \\ & \quad \quad \quad t = \tau, \dots, T. \end{aligned}$$

The first constraint ensures that period 1 is a procurement period. The second constraint set models the requirement that if demand d_t is the last demand satisfied by procurement in some period τ , then period $t+1$ should also be a procurement period. The third set of constraints makes sure that y_{τ} is set to 1 if period τ is a procurement period. We note that the variables $z_{\tau,t}$ will become continuous

in the extended models (see the section titled “Extensions of the DLS Model”), because the ZIO property does not hold anymore.

Figure 3 graphically represents the SP formulation for a three-period problem. The arcs in the figure correspond to the variables y_t and $z_{\tau,t}$ with associated cost K_t and $C_{\tau,t}$, respectively. The optimal cost can be determined by finding the shortest path in the network. As mentioned earlier, the LP relaxation of this formulation provides an integer solution.

The Facility Location Formulation

Krarup and Bilde [10] propose a formulation using the variables $x_{\tau,t}$, where $x_{\tau,t}$ is the procured quantity in period τ to satisfy demand in period t . Furthermore, we let $c_{\tau,t} = p_{\tau} + \sum_{j=\tau}^{t-1} h_j$ denote the variable cost (procurement plus holding cost) to satisfy a unit demand in period t by procurement in period τ . If we again use the setup variables y_t , then the following model is called the *facility location* (FL) formulation:

$$\begin{aligned} \min \quad & \sum_{\tau=1}^T \left(y_{\tau} + \sum_{t=\tau}^T c_{\tau,t} x_{\tau,t} \right) \\ \text{s.t.} \quad & \sum_{\tau=1}^t x_{\tau,t} = d_t \quad t = 1, \dots, T \\ & x_{\tau,t} \leq d_t y_{\tau} \quad \tau = 1, \dots, T; \quad t = i, \dots, T \\ & x_{\tau,t} \geq 0 \quad \tau = 1, \dots, T; \quad t = \tau, \dots, T \\ & y_t \in \{0, 1\} \quad t = 1, \dots, T. \end{aligned}$$

The first constraint set ensures that every demand is satisfied, while the second set of constraints is a set of setup forcing constraints.

Figure 4. The DLS problem represented as a facility location problem.

Figure 4 graphically represents this formulation as a facility location problem (hence the name). The FL problem is a problem in location theory (see also the section titled “Location Analysis” in this encyclopedia) where demands of a set of clients need to be satisfied from a set of facilities. Demand of a client can only be satisfied from a facility if the facility is open. There is a fixed cost to open a facility and a variable transportation cost to satisfy a unit demand of a client by some facility.

If we associate a facility τ and a client t for every time period of the DLS problem, then $x_{\tau,t}$ is the demand of facility t satisfied by facility τ . Furthermore, the setup variable $y_\tau = 1$ ($y_\tau = 0$) corresponds to an open (closed) facility. Note that a facility τ can only satisfy the demand of some period t with $t \geq \tau$ and hence it is a special case of an FL problem. It is shown in Ref. 10 that the LP relaxation of this special FL problem provides an integer solution. This property does not hold for the general FL problem.

SOLUTION METHODS FOR THE DLS MODEL

One way of solving the DLS model is by applying a commercial solver to one of the formulations of the previous section. However, another solution approach is to develop a specialized algorithm. Wagner and Whitin [2] propose a solution method that is based on an important structural property of an optimal solution: the ZIO property. This property states that there is no procurement in a period if there is inventory available at the start of the period, or, more formally, $I_{t-1}x_t = 0$ for

$t = 1, \dots, T$. Zangwill [11] proves that this property holds by using the network flow representation of Fig. 2. He shows that there exists an optimal solution in a single source network with concave costs, such that every node has at most one incoming arc with positive flow. Applying this to the network in Fig. 2 implies that the flow on one of the incoming arcs of node t (I_{t-1} or x_t) is zero. The ZIO property implies that if t is a procurement period, then $x_t = d_{t,k}$ for some $k = t, \dots, T$. In other words, a procurement period always satisfies a consecutive number of demands starting at period t . This property is used to develop a dynamic programming (see also the section titled “Dynamic Programming” in this encyclopedia) algorithm.

To this end, let $C_{s,t}$ be the total cost to satisfy demand in periods $s, \dots, t$ by procurement in period s , that is,

$$C_{s,t} = K_s + p_s d_{s,t} + \sum_{i=s}^{t-1} h_i d_{i+1,t},$$

where the terms correspond to the setup, procurement, and holding costs (we define the empty sum to be 0). Furthermore, let F_t be the minimal cost to satisfy demands in periods $1, \dots, t$. So F_t is the optimal cost of the problem when considering only periods $1, \dots, t$. Then the optimal cost can be determined from the following recursive equation:

$$F_t = \min_{\tau=1, \dots, t} \{F_{\tau-1} + C_{\tau,t}\} \text{ for } t = 1, \dots, T. \quad (2)$$

In the recursion formula, period τ is the last procurement period in the t -period problem. The optimal cost for periods $1, \dots, \tau - 1$ has already been determined and equals $F_{\tau-1}$, while $C_{\tau,t}$ is the cost to satisfy demand in periods $\tau, \dots, t$ by definition. Because we are searching for the minimum cost procurement plan, we take the minimum over all periods $\tau = 1, \dots, t$. The recursion is initialized by $F_0 = 0$ and the optimal cost is equal to F_T .

It is not difficult to see that the running time of this algorithm is $\mathcal{O}(T^2)$. More than 30 years after the Wagner–Whitin algorithm,

faster algorithms were independently developed by Federgruen *et al.* [12,13] and Aggarwal and Park [14]. The algorithms solve the DLS model in a running time of $\mathcal{O}(T \log T)$. In the special case of nonspeculative motives, that is, $p_t + h_t \geq p_{t+1}$, the running time even reduces to $\mathcal{O}(T)$.

EXTENSIONS OF THE DLS MODEL

In practice, lot-sizing problems are often more complex than the DLS problem. Therefore, many extensions have been proposed in the literature to capture reality better. In this section, we discuss some of the extensions and show how these extensions can be incorporated in the formulation using the variables of the basic formulation. We consider the following three categories of extensions: demand, operational, and multiple items. We do not discuss solution approaches to solve the more complex lot-sizing models, because this is beyond the scope of this article.

EXTENSIONS ON DEMAND

Backlogging. If demand is not immediately met but satisfied in a later period, then the demand is satisfied by backlogging [11]. This means that demand in a period can now be satisfied by procurement, inventory, or backlogging. So backlogging can be considered as negative inventory. If I_t^- is the amount backlogged in period t , then the inventory balance constraints change to

$$x_t + I_{t-1} + I_t^- = d_t + I_t + I_{t-1}^- \quad \text{for } t = 1, \dots, T.$$

In the network flow representation of Fig. 2, backlogging can be represented by arcs from node t to $t-1$ for $t = 2, \dots, T$.

Stockouts. A stockout occurs if demand is not satisfied or backlogged but lost [15]. Some models allow for partial stockouts, which means that a portion of the demand is satisfied. Let l_t be the

amount of lost-sales in period t . Then partial stockouts are imposed by the constraints

$$\begin{aligned} I_{t-1} + x_t + l_t &= d_t + I_t \\ &\text{for } t = 1, \dots, T, \\ 0 \leq l_t &\leq d_t \quad \text{for } t = 1, \dots, T. \end{aligned}$$

The variables l_t are included in the objective function to account for the stockout costs. For example, the coefficient of l_t in the objective function may represent the selling price of the item.

Time Windows. Sometimes demand does not have to be satisfied in a single time period, but an earliest and latest delivery period are specified [16]. Let D_j ($j = 1, \dots, M$) be the demand that needs to be satisfied in the time window $[b_j, e_j] = \{t = 1, \dots, T : b_j \leq t \leq e_j\}$. Note that the number of time windows M equals at most $\frac{1}{2}T(T+1)$ because $1 \leq b_j \leq e_j \leq T$. We need some additional variables to formulate the time window constraints. Let $w_{t,j}$, $j = 1, \dots, M$ and $b_j \leq t \leq e_j$, be the procurement quantity in period t to satisfy demand D_j . Then the constraints

$$\sum_{t=b_j}^{e_j} w_{t,j} = D_j \quad \text{for } j = 1, \dots, M$$

together with the modified demand constraints

$$I_{t-1} + x_t = \sum_{j: b_j \leq t \leq e_j} w_{t,j} + I_t \quad \text{for } t = 1, \dots, T,$$

ensure that demand is met in the specified time window.

Another application of time windows is considered in Ref. 17, where demand D_j needs to be satisfied in period e_t by procurement in the time window $[b_j, e_j]$. This is called *lot-sizing with delivery time windows*. Again, let $w_{t,j}$, $j = 1, \dots, M$ and $b_j \leq t \leq e_j$ be the procurement amount in period t to satisfy D_j .

Furthermore, let $\Delta_t = \sum_{j:e_j=t} D_j$ be the total demand that needs to be satisfied in period t . To formulate the DLS model with delivery time windows, the demand constraints change to

$$\begin{aligned} x_t + I_{t-1} &= \Delta_t + I_t, & \text{for } t = 1, \dots, T, \\ \sum_{t=b_j}^{e_j} w_{t,j} &= D_j, & \text{for } j = 1, \dots, M. \end{aligned}$$

and we need the constraints

$$x_t = \sum_{j:b_t \leq j \leq e_t} w_{t,j} \text{ for } t = 1, \dots, T$$

to link the x_t and $w_{t,j}$ variables.

Operational Extensions

Procurement Capacity. In the DLS model, it is implicitly assumed that the procurement capacity is infinite. However, the capacity in a period (such as the number of man-hours) is limited in practice. This leads to the additional constraints

$$x_t \leq C_t \text{ for } t = 1, \dots, T,$$

with C_t the procurement capacity in period t . Because of this constraint, the well-known ZIO property does not hold anymore and the structure of an optimal solution becomes more complicated. In fact, in the case of time-varying capacities, the problem becomes $\mathcal{NP}$ -hard [18]. The computational complexity of the capacitated DLS model is studied in more detail in Ref. 19. Complexity results are derived for families of problem instances based on the characteristics of the cost parameters and capacities.

Lower and Upper Bounds on Inventory.

The warehouse where the items are stored also has a finite capacity, which leads to an upper bound on the inventory in a period [20]. On the other hand, if a firm applies a (deterministic) lot-sizing model in a stochastic demand setting, lower bounds on inventory may be a heuristic way to set safety

stocks. This can be captured in the constraints

$$L_t \leq I_t \leq U_t \text{ for } t = 1, \dots, T,$$

with L_t (U_t) the lower (upper) bound on inventory in period t .

Multiple Items

Multiple Items. Instead of determining the timing and procurement quantities for a single item, multiple items are often involved in procurement planning. This can be modeled by introducing the additional index i for the parameters and decision variables. So the variables x_t^i , y_t^i , and I_t^i denote the procurement quantity, setup decision, and inventory of item i in period t , respectively. The capacity constraints change to

$$\sum_{i=1}^n x_t^i \leq C_t \text{ for } t = 1, \dots, T,$$

if the items share the same capacity. If only one item can be produced in a period, then the constraints

$$\sum_{i=1}^n y_t^i \leq 1 \text{ for } t = 1, \dots, T,$$

need to be added, where n is the number of items. This type of model is called a *small-bucket model*. This is in contrast to a *big-bucket model*, where all items can be produced in a period. Within the small-bucket models, we distinguish two types of models: (i) if production occurs, it must be at full capacity (this is called the *discrete lot-sizing and scheduling problem*) and (ii) if production occurs, it can be at any level within the capacity limits.

Startups. A startup or changeover occurs if a machine needs to be setup and has not been setup for the item in the previous period. So there is no startup if

the same item is produced in two consecutive periods. Additional setup cost or setup time may be associated with a startup. Let $z_t^i = 1$ denote a startup for item i in period t and $z_t^i = 0$ otherwise. If the z_t^i variables appear with a positive coefficient in the objective function, then the constraints

$$z_t^i \geq y_t^i - y_{t-1}^i \text{ for } t = 1, \dots, T; \\ i = 1, \dots, n,$$

model the startup. Clearly, startups can also be considered for the single-item version of the problem [21].

Setup Times. Setting up a machine may not only induce cost but may also consume part of the production capacity [3,22]. For example, capacity is lost due to cleaning, changing machine settings, inspection, testing, and so on. To account for setup times, the capacity constraints change to

$$\sum_{i=1}^n (s_t^i y_t^i + v_t^i x_t^i) \leq C_t \text{ for } t = 1, \dots, T,$$

with s_t^i the capacity of setting up the machine for item i and v_t^i the variable capacity consumption of item i in period t .

It is not difficult to see that the extensions in the sections “Extensions on Demand” and “Operational Extensions” can be easily generalized to the multi-item case.

CONCLUDING REMARKS

In the previous section, we considered several extensions of the DLS model and the consequences to the basic formulation. Clearly, the extended DLS models are more difficult to solve than the DLS model. Some practical lot-sizing problems can be effectively solved by mixed integer programming via tight formulations and valid inequalities [23,24]. To solve more complicated DLS models, several other advanced techniques are proposed in the literature. These techniques include,

for example, Dantzig–Wolfe decomposition, Lagrange relaxation, and column generation (see also the section titled “Large-Scale Optimization” in this encyclopedia), or metaheuristics (see also the section titled “Heuristics and Meta-Heuristics” in this encyclopedia) such as tabu search, simulated annealing, and genetic algorithms [25].

A drawback of lot-sizing models is that they are not able to capture uncertainty in the problem parameters. For example, the demand may not be known over the planning horizon or the capacity may be uncertain because of technical breakdowns. Therefore, one should be careful when applying a lot-sizing model and ascertain whether the assumptions of the model are a good representation of reality. If there is considerable uncertainty, one should apply a stochastic inventory model (see the section titled “Inventory Management and Control” in this encyclopedia). It should be mentioned that recently a stochastic lot-sizing model has been proposed, where stochasticity is captured in a scenario tree [26]. Each level of the scenario tree corresponds to a period t and each scenario occurs with some probability. The objective is to find a procurement plan that minimizes the expected lot-sizing costs.

Finally, the number of possible extensions of the DLS model is much larger than the ones presented in this article. For a comprehensive list of possible extensions and corresponding references (more than 240), we refer to Ref. 27.

LOVÁSZ-SCHRIJVER REFORMULATION

MADHUR TULSIANI
Institute for Advanced Study,
Princeton, New Jersey

A common technique for solving a 0–1 integer program is to work with its linear programming (LP) relaxation, and then relate the optimum of the relaxation to that of the integer program. Consider an integer program with a feasible region described by the m inequalities of the form $\mathbf{a}_i \cdot \mathbf{x} - b_i \geq 0$ in variables $x_1, \dots, x_n \in \{0, 1\}$. In formulating a convex relaxation of this problem, one would like to optimize over the convex hull of the integral solutions to the above program (since for a linear objective function, the optimum over the integral solutions would be equal to the optimum over their convex hull). Most LP relaxations are obtained by simply relaxing the domain of the variables to be $[0, 1]$ instead of $\{0, 1\}$. However, in that case the resulting polytope may contain points that are outside this convex hull.

Starting from the works of Gomory [1] and Chvátal [2], a large amount of research has been done on developing methods that generate additional constraints valid for the integral solutions of the problem, to obtain tighter and tighter convex relaxations. Lovász and Schrijver [3] describe a powerful technique for generating additional inequalities. Given a program as above, let $\mathcal{P}$ denote the feasible polytope for the linear program obtained by relaxing the domain of the variables to be $[0, 1]$. Using the fact that any integer solution must satisfy $x_j^2 = x_j$ for all $j \in \{1, \dots, n\}$, it is easy to check that for $\lambda_{ij}, \sigma_{ij} \geq 0$, and $\mu_j \in \mathbb{R}$, any quadratic inequality of the form

$$\sum_{\substack{1 \leq i \leq m \\ 1 \leq j \leq n}} \lambda_{ij} (\mathbf{a}_i \cdot \mathbf{x} - b_i) x_j \\ + \sum_{\substack{1 \leq i \leq m \\ 1 \leq j \leq n}} \sigma_{ij} (\mathbf{a}_i \cdot \mathbf{x} - b_i) (1 - x_j)$$

$$+ \sum_{1 \leq j \leq n} \mu_j (x_j^2 - x_j) \geq 0 \quad (1)$$

is also valid for any integer solution to the program. The Lovász–Schrijver reformulation automatically adds any *linear* inequalities which can be derived as above, to the linear program describing $\mathcal{P}$. They also define a stronger version that adds even more constraints giving a semidefinite program (SDP).

Thinking of the strengthening as an operator applied to a polytope, we can also apply it iteratively, yielding a sequence of stronger and stronger relaxations, often referred to as *hierarchies* of linear and semidefinite programs. We describe two such hierarchies defined by Lovász and Schrijver, known as the *LS* (linear) and *LS₊* (semidefinite) hierarchies. These hierarchies have been studied in different contexts, such as algorithmic analysis, computational complexity, and proof complexity, and somewhat different ways of looking at them were considered in each of these. The rest of this article is devoted to describing some of these viewpoints.

DESCRIPTION OF THE HIERARCHIES

To describe these hierarchies, it will be more convenient to work with *convex cones* rather than convex subsets of $[0, 1]^n$. Recall that a *cone* is a subset K of $\mathbb{R}^d$ such that if $\mathbf{x}, \mathbf{y} \in K$ and $\alpha, \beta \geq 0$ then $\alpha\mathbf{x} + \beta\mathbf{y} \in K$. If we are interested in a convex set $\mathcal{P} \subseteq [0, 1]^n$ (which might be the feasible region of our starting convex relaxation), we first convert it into a cone in $\mathbb{R}^{n+1}$. We define

$$\text{cone}(\mathcal{P}) = \{ \mathbf{y} = (\lambda, \lambda x_1, \dots, \lambda x_n) \mid \lambda \geq 0, \\ (x_1, \dots, x_n) \in \mathcal{P} \}.$$

It is easy to check that all the quadratic constraints of the form described in Equation (1) would follow if we could impose constraints of the form $x_j^2 = x_j$ for each $j \in \{1, \dots, n\}$. However, this constraint is neither linear nor convex. We thus impose linear constraints

implied by this, by introducing auxiliary variables $Y_{i,j}$, which are supposed to be equal to the product $x_i x_j$ when $\mathbf{y} = (1, x_1, \dots, x_n)$. We require that $Y_{i,i} = y_i$. Also, if Y_i denotes the i th row of the matrix Y , then it must be true that $(Y_i/y_i)_{1\dots n} \in \mathcal{P}$ when $y_i \neq 0$, where by $(Y_i/y_i)_{1\dots n}$ we denote the vector consisting of the last n coordinates of (Y_i/y_i) . This is equivalent to saying that $Y_i \in \text{cone}(\mathcal{P})$. Similarly, $y_i \neq y_0$ must imply $((Y_0 - Y_i)/(y_0 - y_i))_{1\dots n} \in \mathcal{P}$ and hence $Y_0 - Y_i \in \text{cone}(\mathcal{P})$. Lovász and Schrijver use this to define two operators N and N_+ , such that for a starting cone K , $N_+(K) \subseteq N(K) \subseteq K$.

Definition 1. For a cone $K \subseteq \mathbb{R}^{n+1}$ we define the set $N(K)$ (also a cone in $\mathbb{R}^{n+1}$) as follows: a vector $\mathbf{y} = (y_0, \dots, y_n) \in \mathbb{R}^{n+1}$ is in $N(K)$ iff there is a matrix $Y \in \mathbb{R}^{(n+1) \times (n+1)}$ such that

1. Y is symmetric.
2. For every $i \in \{0, 1, \dots, n\}$, $Y_{0,i} = Y_{i,i} = y_i$.
3. Each row Y_i is an element of K .
4. Each vector $Y_0 - Y_i$ is an element of K .

In such a case, Y is called the *protection matrix* of $\mathbf{y}$. If, in addition, Y is positive semidefinite, then $\mathbf{y} \in N_+(K)$. We define $N^0(K)$ and $N_+^0(K)$ as K , and $N^t(K)$ ($N_+^t(K)$) as $N(N^{t-1}(K))$ (respectively, $N_+(N_+^{t-1}(K))$).

Remark 1. Lovász and Schrijver also define a third operator which they denote by N_0 , which is weaker than the ones described here. It is defined in a manner similar to the N and N_+ operators, except that the protection matrix Y is not required to be symmetric. However, we shall not discuss this here.

If $\mathbf{y} = (\lambda, \lambda x_1, \dots, \lambda x_n) \in \mathbb{R}^{n+1}$ for $x_1, \dots, x_n \in \{0, 1\}$, then we can set $Y_{i,j} = \lambda \cdot x_i x_j$. Such a matrix Y is clearly positive semidefinite, and it satisfies $Y_{i,i} = \lambda x_i^2 = \lambda x_i = y_i$. Also $Y_i = x_i \cdot \mathbf{y}$ and $Y_0 - Y_i = (1 - x_i) \cdot \mathbf{y}$. Hence they lie in the same cone as $\mathbf{y}$.

In the case when $\mathcal{P} \in \mathbb{R}^n$ is a polytope defined by linear constraints and $\text{cone}(\mathcal{P})$ is the corresponding cone, we often use

the notation $N^t(\mathcal{P})$ and $N_+^t(\mathcal{P})$ to denote $N^t \text{cone}(\mathcal{P}) \cap \{y_0 = 1\}$ and $N_+^t \text{cone}(\mathcal{P}) \cap \{y_0 = 1\}$, respectively. The following claim characterizes $N(\mathcal{P})$ and $N_+(\mathcal{P})$ in terms of the additional inequalities imposed by the reformulation.

Claim 1. Let $\mathcal{P} \in \mathbb{R}^n$ be a polytope defined by the constraints $\mathbf{a}_i \cdot \mathbf{x} - b_i \geq 0$ for $i \in \{1, \dots, m\}$. Then for a vector $\mathbf{x} \in \mathbb{R}^n$,

1. $\mathbf{x} \in N(\mathcal{P})$ iff it satisfies all linear equalities $\mathbf{c} \cdot \mathbf{x} - d \geq 0$ which can be derived as

$$\begin{aligned} \mathbf{c} \cdot \mathbf{x} - d = & \sum_{\substack{1 \leq i \leq m \\ 1 \leq j \leq n}} \lambda_{ij} (\mathbf{a}_i \cdot \mathbf{x} - b_i) x_j \\ & + \sum_{\substack{1 \leq i \leq m \\ 1 \leq j \leq n}} \sigma_{ij} (\mathbf{a}_i \cdot \mathbf{x} - b_i) (1 - x_j) \\ & + \sum_{1 \leq j \leq n} \mu_j (x_j^2 - x_j) \end{aligned}$$

for $\lambda_{ij}, \sigma_{ij} \geq 0$ and $\mu_j \in \mathbb{R}$.

2. $\mathbf{x} \in N_+(\mathcal{P})$ iff it satisfies all linear equalities $\mathbf{c} \cdot \mathbf{x} - d \geq 0$ which can be derived as

$$\begin{aligned} \mathbf{c} \cdot \mathbf{x} - d = & \sum_{\substack{1 \leq i \leq m \\ 1 \leq j \leq n}} \lambda_{ij} (\mathbf{a}_i \cdot \mathbf{x} - b_i) x_j \\ & + \sum_{\substack{1 \leq i \leq m \\ 1 \leq j \leq n}} \sigma_{ij} (\mathbf{a}_i \cdot \mathbf{x} - b_i) (1 - x_j) \\ & + \sum_{1 \leq j \leq n} \mu_j (x_j^2 - x_j) + \sum_k (\mathbf{g}_k \cdot \mathbf{x} - h_k)^2 \end{aligned}$$

for $\lambda_{ij}, \sigma_{ij} \geq 0$, $\mu_j, h_k \in \mathbb{R}$ and $\mathbf{g}_k \in \mathbb{R}^n$.

The characterization in terms of the inequalities is particularly useful when reasoning about these hierarchies as proof systems for (say) proving that a certain integer program has no integral solutions. The rules for deriving the inequalities characterizing $N(\mathcal{P})$ from those characterizing $\mathcal{P}$ can then be thought of as the derivation rules of this proof system. One is then interested in the smallest t such that $N^t(\mathcal{P})$ is empty (called the *rank* of the

proof system) and in the minimum number of inequalities needed (called the *size* of the proof) to derive a convex system of inequalities that has no feasible solution. We discuss two different ways of viewing Definition 1 below.

The Prover–Adversary Game

It is sometimes convenient to think of the LS and LS_+ hierarchies in terms of a game between two parties called a *prover* and an *adversary*. This formulation was first used by Buresh-Oppenheim *et al.* [4] who used it to prove lower bounds on the LS_+ procedure as a proof system. For example, the following is a formulation that is convenient to use for proving that a certain vector belongs to $N_+^t(K)$ for a cone $K \subseteq \mathbb{R}^{n+1}$. The formulation remains the same for talking about $N(K)$, except that we omit the positive semidefiniteness constraint in the matrix below.

A *prover* is an algorithm that, on an input vector $(y_0, \dots, y_n)$, either fails or outputs a matrix $Y \in \mathbb{R}^{(n+1) \times (n+1)}$ and a set of vectors $O \subseteq \mathbb{R}^{n+1}$ such that

1. Y is symmetric and positive semidefinite.
2. $Y_{i,i} = Y_{0,i} = y_i$.
3. Each vector Y_i and $Y_0 - Y_i$ is a nonnegative linear combination of vectors of O .
4. Each element of O is in K .

Now, consider the following game played by a prover against another party called the *adversary*. We start from a vector $\mathbf{y} = (y_0, \dots, y_n)$, and the prover, on input $\mathbf{y}$, outputs Y and O as before. Then the adversary chooses a vector $\mathbf{z} \in O$, and the prover, on input $\mathbf{z}$, outputs a matrix Y' and a set O' , and so on. The adversary *wins* when the prover fails to output a matrix and vectors with the required properties.

Lemma 1. *Suppose that there is a prover such that, starting from a vector $\mathbf{y} \in K$, every adversary strategy requires at least $t + 1$ moves to win. Then $\mathbf{y} \in N^t(K)$.*

Proof. We proceed by induction on t , with $t = 0$ being the simple base case. Suppose that,

for every adversary, it takes at least $t + 1$ moves to win, and let Y and O be the outputs of the prover on input $\mathbf{y}$. Then, for every element $\mathbf{z} \in O$, and every prover strategy, it takes at least t moves to win starting from $\mathbf{z}$. By the inductive hypothesis, each element of O is in $N_+^{t-1}(K)$, and since $N_+^{t-1}(K)$ is closed under nonnegative linear combinations, the vectors Y_i and $Y_0 - Y_i$ are all in $N_+^{t-1}(K)$, and so Y is a protection matrix that shows that $\mathbf{y}$ is in $N_+^t(K)$.

While the framework is simply a restatement of the conditions defining $N(K)$ and $N_+(K)$, it turns out to be surprisingly convenient to think of many arguments in terms of strategies for this game. Also, note that we added the set O in the description of the conditions. In many proofs, it is convenient to think of O as a set of vectors satisfying some structural invariant. Often it may be easier to exhibit matrices Y for vectors satisfying some invariants, than for arbitrary vectors in K .

The View in Terms of Local Probability Distributions

Yet another view of the conditions which has been useful in reasoning about optimization problems is the interpretation of solutions as “locally conditioned probability distributions.” Let $\mathbf{x} \in \mathcal{P}$ be expressible as $\mathbf{x} = \sum_i \lambda_i \mathbf{z}^{(i)}$ where $\sum_i \lambda_i = 1$ and $\forall i, \mathbf{z}^{(i)} \in \mathcal{P} \cap \{0, 1\}^n, \lambda_i \geq 0$. Then, we can consider a random variable $\mathbf{z}$ which takes value $\mathbf{z}^{(i)}$ with probability λ_i . For $j \in \{1, \dots, n\}$, the numbers x_j then are equal to $\mathbf{P}[z_j = 1]$, that is, the marginals of this distribution.

To prove that $\mathbf{x} \in \mathcal{P}$, we then require a matrix $Y \in \mathbb{R}^{n+1}$ which satisfies the conditions stated in the section titled “The Prover–Adversary Game”. For each $\mathbf{z}^{(i)}$ such a matrix $Y^{(i)}$ can be given as $Y^{(i)} = (1, \mathbf{z}^{(i)})(1, \mathbf{z}^{(i)})^T$ where $(1, \mathbf{z}^{(i)}) \in \mathbb{R}^{n+1}$. The matrix Y for $\mathbf{x}$ can then be exhibited as $Y = \sum_i \lambda_i Y^{(i)}$, where each entry $Y_{ij} = \mathbf{P}[(z_i = 1) \wedge (z_j = 1)]$. Arguing that the vector $Y_i \in \text{cone}(\mathcal{P})$ is then equivalent to arguing that the vector $\mathbf{x}^{(i,1)} \in \mathbb{R}^n$ with

$$x_j^{(i,1)} = Y_{ij}/x_i = \mathbf{P}[z_j = 1 | z_i = 1]$$

Figure 1. A comparison of the hierarchies.

is in $\mathcal{P}$. Similarly, $Y_0 - Y_i \in \text{cone}(\mathcal{P})$ is equivalent to proving that the vector $\mathbf{x}^{(i,0)}$ with coordinates $x_j^{(i,0)} = (Y_{0j} - Y_{ij})/(1 - x_i) = \mathbf{P}[z_j = 1 | z_i = 0]$ is in $\mathcal{P}$.

Thus, the conditions for membership in $N(\mathcal{P})$ and $N_+(\mathcal{P})$ can be thought of as conditions for checking that a vector $\mathbf{x}$ indeed represents the marginals of a distribution over $\mathcal{P} \cap \{0, 1\}^n$. The test is the existence of conditional distributions, conditioned on each coordinate i being either 0 or 1. Similarly, exhibiting membership in $N^t(\mathcal{P})$ then corresponds to exhibiting distributions after conditioning on any t variables instead of just one.

Combining this with the prover–adversary framework, we can think that at each step, the adversary conditions a particular variable to be 0 or 1. The task of the prover is then to provide a matrix corresponding to the conditional distribution. We must emphasize that this is *not an exact characterization* of the hierarchies, but this intuition has been quite useful in arguing about their performance on optimization problems, as discussed in the section titled “Hardness Results for Optimization Problems.”

Relation to Sherali–Adams and Lasserre Hierarchies

Hierarchies of relaxations similar to the ones by Lovász and Schrijver were also defined by Sherali and Adams [5] and Lasserre [6]. For a starting linear program with feasible region $\mathcal{P}$, let $\text{SA}^t(\mathcal{P})$ and $\text{Las}^t(\mathcal{P})$ denote the feasible regions of the relaxations obtained at the t th level of these hierarchies. The set $\text{SA}^t(\mathcal{P})$ can be described as the projection of the feasible region of a linear program in

$n^{O(t)}$ variables, while $\text{Las}^t(\mathcal{P})$ is the projection of the feasible set for a semidefinite program in $n^{O(t)}$ dimensions.

It is also known that $\text{SA}^t(\mathcal{P}) \subseteq N^t(\mathcal{P})$ and $\text{Las}^t(\mathcal{P}) \subseteq N_+^t(\mathcal{P})$ and thus the Sherali–Adams and Lasserre hierarchies provide tighter relaxations, respectively, than the LS and LS_+ hierarchies. Figure 1 shows the relationships between these different hierarchies, with an arrow $A \rightarrow B$ indicating that $A \supseteq B$ and thus B is tighter than A . A more detailed comparison can be found in the excellent survey by Laurent [7].

ALGORITHMIC ASPECTS AND APPLICATIONS

We first note that if K is defined by a linear program with m constraints in the $n + 1$ variables $y_0, \dots, y_n$, then $N(K)$ is defined by a linear program with $O(mn)$ constraints in the $O(n^2)$ variables corresponding to the entries of the matrix Y . Similarly, $N_+(K)$ is defined by a semidefinite program in Y with $O(mn)$ constraints. More generally, Lovász and Schrijver show the following.

Theorem 1. *Given a weak separation oracle for the cone K , the weak separation problem for $N(K)$ and $N_+(K)$ can be solved in polynomial time.*

Hence, whenever it is possible to easily optimize over the cone K , one can also optimize over the cone $N(K)$ (or $N_+(K)$) with a polynomial overhead. Using the above, it is also easy to deduce that weak separation oracles for $N^t(K)$ and $N_+^t(K)$ can be implemented in time $n^{O(t)}$, given one for K running in polynomial time. For a convex region $\mathcal{P} \subseteq \mathbb{R}^n$, let $K_I \subseteq \mathbb{R}^{n+1}$ denote the cone generated by the integral vectors $\{(1, \mathbf{x}) | \mathbf{x} \in \mathcal{P} \cap \{0, 1\}^n\}$ and let $K = \text{cone}(\mathcal{P})$. Then, it is known that n applications of $N(\cdot)$ are sufficient to converge to K_I .

Theorem 2. $N^n(K) = N_+^n(K) = K_I$.

However, note that n applications take time $n^{O(n)}$, which is super-exponential in n . For general cones, this bound is known to be tight for both N and N_+ operators, as was shown by

Cook and Dash [8] and also by Goemans and Tunçel [9]. Typically, the interesting question is whether, for a given problem, optimizing over $N^t(K)$ or $N_+^t(K)$ for a small t can give some nontrivial approximation guarantee.

Application to Independent Set

As an example, we consider the constraints obtained by applying the $N(\cdot)$ and $N_+(\cdot)$ operators to the feasible set of the LP relaxation for maximum independent set, which is the problem of finding the largest subset of vertices in a graph not containing an edge (also known as the *maximum stable set* problem). Let $G = (V, E)$ be a graph on n vertices. Then, the linear programming relaxation for the maximum independent set problem has variables $x_1, \dots, x_n \in [0, 1]$ and constraints $x_i + x_j \leq 1$ for all $(i, j) \in E$. We denote the feasible region of these constraints as $\text{IS}(G)$. The objective is to maximize the sum $\sum_i x_i$.

The set cone $\text{IS}(G)$ is then given by the inequalities $0 \leq y_i \leq y_0$ for all $i \in \{1, \dots, n\}$ and $y_i + y_j \leq y_0$ for all $(i, j) \in E$. We are interested in the sets given by $N(\text{IS}(G))$ and $N_+(\text{IS}(G))$.

There are also various additional constraints that are satisfied by an integer solution to the independent set problem. Lovász and Schrijver consider the so-called *odd-cycle constraints* and *clique constraints* and show that they are implied by one application of $N(\cdot)$ and $N_+(\cdot)$, respectively. The former type of constraints say that if C is a set of vertices forming a cycle of odd length, then $\sum_{i \in C} x_i \leq (|C| - 1)/2$. The latter require that if B is a set of vertices forming a clique, then $\sum_{i \in B} x_i \leq 1$. We give a proof below for the sake of illustration.

Claim 2. *For a graph $G = (V, E)$, let $\mathbf{x} = (x_1, \dots, x_n)$ be a vector in $\text{IS}(G)$. Then*

1. *If $\mathbf{x} \in N(\text{IS}(G))$, then for every odd cycle C in G , $\sum_{i \in C} x_i \leq (|C| - 1)/2$.*
2. *If $\mathbf{x} \in N_+(\text{IS}(G))$, then for every clique B in G , $\sum_{i \in B} x_i \leq 1$.*

Proof. For this part, it is convenient to think of $N(\text{IS}(G))$ in terms of the rules for deriving

new inequalities by a combination of old ones, as given in Claim 1. Let $C = \{i_1, \dots, i_k\}$ be a cycle of odd length in the graph. Since $i_1, \dots, i_{k-1}$ can be covered by $(k-1)/2$ edges, adding their inequalities we have $x_{i_1} + \dots + x_{i_{k-1}} \leq (k-1)/2$. Similarly, $x_{i_2} + \dots + x_{i_{k-2}} \leq (k-3)/2$. Using these and Claim 1, we get that $(x_1, \dots, x_n)$ must satisfy

$$\begin{aligned} & \left(\sum_{j=1}^{k-1} x_{i_j} - \frac{(k-1)}{2} \right) (1 - x_{i_k}) \\ & + \left[\left(\sum_{j=2}^{k-2} x_{i_j} - \frac{(k-3)}{2} \right) + (x_{i_1} + x_{i_k} - 1) \right. \\ & \quad \left. + (x_{i_{k-1}} + x_{i_k} - 1) \right] x_{i_k} \\ & - 2(x_{i_k}^2 - x_{i_k}) \leq 0 \end{aligned}$$

Simplifying the above equation yields $\sum_{j=1}^k x_{i_j} \leq (k-1)/2$.

For the second part, it is more convenient to think of $\mathbf{x} \in N_+(\text{IS}(G))$ in terms of the protection matrix Y certifying that $\mathbf{y} = (1, x_1, \dots, x_n) \in N(\text{cone}(\text{IS}(G)))$, as in Definition 1. Since the matrix must be positive semidefinite, we consider its Gram decomposition, say given by the vectors $\mathbf{v}_0, \dots, \mathbf{v}_n$. The conditions $Y_{i,0} = Y_{i,i} = y_i$ imply that $|\mathbf{v}_0|^2 = 1$ and $\langle \mathbf{v}_0, \mathbf{v}_i \rangle = \|\mathbf{v}_i\|^2 = x_i$.

If (i, j) is an edge in the graph, then since Y_i must be in the cone $\text{IS}(G)$, we get $Y_{i,i} + Y_{i,j} \leq Y_{i,0}$ and hence $Y_{i,j} \leq 0$. However, since a vector in the cone must have nonnegative entries, we must have $Y_{i,j} = \langle \mathbf{v}_i, \mathbf{v}_j \rangle = 0$ for any edge (i, j) . Thus, all the vectors corresponding to vertices in a clique must be orthogonal. By Pythagoras' theorem,

$$\begin{aligned} \sum_{i \in B, |\mathbf{v}_i| > 0} \frac{\langle \mathbf{v}_0, \mathbf{v}_i \rangle^2}{|\mathbf{v}_i|^2} & \leq |\mathbf{v}_0|^2 \implies \sum_{i \in B, x_i > 0} \frac{x_i^2}{x_i} \leq 1 \\ & \implies \sum_{i \in B} x_i \leq 1. \end{aligned}$$

The graphs for which the clique constraints exactly characterize the convex hull of 0–1 independent sets are called *perfect* graphs. Hence, the above equation shows that

optimizing over $N_+(\text{IS}(G))$, one finds exactly the size of the maximum independent set for a perfect graph G . Similarly, by optimizing over $N(\text{IS}(G))$, one finds the maximum independent set in graphs for which the odd-cycle constraints characterize the 0–1 independent sets. Such graphs are known as *h-perfect*.

Deriving the SDP relaxation for Sparsest Cut

Alekhovich *et al.* [10] sketch how the well-known semidefinite programming relaxation for sparsest cut by Arora *et al.* [11] can be derived by three levels of the LS_+ hierarchy starting from a basic linear program. We give a proof below showing that in fact, one level of the LS_+ hierarchy already derives the relaxation in Arora *et al.* [11].

Sparsest cut is the problem of finding a cut $(S, \bar{S})$ minimizing $|E(S, \bar{S})|/|S|$, the ratio of the number of outgoing edges to the size of S . In the discussion below, we instead describe the argument for the c -balanced separator problem, which is known to be closely related to sparsest cut [11–13]. Instead of asking for the sparsest cut of any size, the c -balanced separator problem asks for the sparsest cut with at least cn vertices on each side of the cut. For a graph $G = (V, E)$ on n vertices, the linear program involves $n + \binom{n}{2}$ variables: $x_i \in [0, 1]$ for each vertex i , representing which side of the cut it is, and $d_{ij} \in [0, 1]$ for every pair $\{i, j\}$ of vertices representing the distance between them (which in an integral solution is 0 if they are on the same side and 1 otherwise).

The constraint $\sum d_{ij} \geq c(1 - c)n^2$ imposes the condition (on integer solutions) that the number of vertices on each side of the cut is at least cn . Note that the program mentioned in Fig. 2 is quite weak (in fact its integrality gap, as defined in the section titled “Hardness Results for Optimization Problems” is infinite). This can be seen by using the solution $x_i = 1/2$ for all i and $d_{ij} = 0$ when $(i, j) \in E$ and $d_{ij} = 1$ otherwise. This is a feasible solution with objective value 0 for any graph in which $|E| \leq \binom{n}{2} - c(1 - c)n^2$, while the integer optimum may be arbitrarily large. Adding the inequality $d_{ij} + d_{jk} \geq d_{ik}$ for every triple i, j, k makes it at least as strong as the linear program used by Leighton and

Rao [12,13], which was shown to achieve an $O(\log n)$ approximation. However, even without this added inequality, one application of the N_+ operator derives the relaxation in Arora *et al.* [11], which achieves an $O(\sqrt{\log n})$ approximation.

Arora *et al.* [11] use a semidefinite program with $n \times n$ semidefinite matrix Y whose Gram decomposition is given by the vectors $\mathbf{v}_1, \dots, \mathbf{v}_n$. A solution to their program would be a feasible solution to the above LP if we take $x_i = |\mathbf{v}_i|^2$ and $d_{ij} = |\mathbf{v}_i - \mathbf{v}_j|^2$. They also impose the additional inequality that $|\mathbf{v}_i - \mathbf{v}_j|^2 + |\mathbf{v}_j - \mathbf{v}_k|^2 \geq |\mathbf{v}_i - \mathbf{v}_k|^2$. We argue below that this inequality is derived by one application of N_+ .

Claim 3. *Let $(1, \mathbf{x}, \mathbf{d}) \in N_+(\text{cone}(BS(G)))$ and let Y be its protection matrix with the Gram decomposition $\{\mathbf{v}_0, \{\mathbf{v}_i\}_{i \in V}, \{\mathbf{v}_{ij}\}_{\{i,j\} \in \binom{V}{2}}\}$. Then the vectors $\mathbf{v}_1, \dots, \mathbf{v}_n$ satisfy for all i, j, k*

$$d_{ij} = |\mathbf{v}_i - \mathbf{v}_j|^2 \quad \text{and} \quad |\mathbf{v}_i - \mathbf{v}_j|^2 + |\mathbf{v}_j - \mathbf{v}_k|^2 \geq |\mathbf{v}_i - \mathbf{v}_k|^2.$$

Proof. If $x_1, \dots, x_n$ were indeed an integer solution, we would have $d_{ij} = (x_i - x_j)^2$, which is 1, when exactly one of x_i, x_j is 1. To derive this for an integer solution, we use $d_{ij} \leq (1 - x_i) + (1 - x_j)$ and $d_{ij} \leq x_i + x_j$ to get $d_{ij}x_j \leq (2 - x_i - x_j)x_j$ and $d_{ij}(1 - x_j) \leq (x_i + x_j)(1 - x_j)$. Adding these two, and using $x_i^2 = x_i$ and $x_j^2 = x_j$, we get $d_{ij} \leq (x_i - x_j)^2$. Similarly, starting with the inequalities $d_{ij} \geq x_i - x_j$ and $d_{ij} \geq x_j - x_i$, we can get $d_{ij} \geq (x_i - x_j)^2$.

The proof essentially simulates the “linearized” version of this reasoning, replacing a quadratic term $x_i x_j$ by the entry $Y_{i,j}$ of the matrix. We also use $Y_{i,jk}$ to refer to the entry of the matrix corresponding to variables x_i and d_{jk} . Since $Y_j \in \text{cone}(BS(G))$ and $Y_0 - Y_j \in \text{cone}(BS(G))$, we get

$$Y_{j,ij} \leq 2Y_{j,0} - Y_{j,i} - Y_{j,j} \quad \text{and} \\ Y_{0,ij} - Y_{j,ij} \leq (Y_{0,i} - Y_{j,i}) + (Y_{0,j} - Y_{j,j}).$$

Again, adding the two and using $Y_{i,i} = Y_{0,i}$ and $Y_{j,j} = Y_{0,j}$ we get

$$d_{ij} = Y_{0,ij} \leq Y_{i,i} + Y_{j,j} - 2Y_{i,j} = |\mathbf{v}_i - \mathbf{v}_j|^2.$$

$$\begin{array}{ll}
\text{minimize} & \sum_{(i,j) \in E} d_{ij} \\
\text{subject to} & d_{ij} \leq x_i + x_j \quad \forall \{i, j\} \\
& d_{ij} \leq (1 - x_i) + (1 - x_j) \quad \forall \{i, j\} \\
& d_{ij} \geq x_i - x_j \quad \forall \{i, j\} \\
& d_{ij} \geq x_j - x_i \quad \forall \{i, j\} \\
& \sum_{\{i,j\} \in \binom{V}{2}} d_{ij} \geq c(1-c)n^2 \\
& x_i, d_{ij} \in [0, 1]
\end{array}$$

Figure 2. LP relaxation for balanced separator.

The proof of the inequality in the other direction is similar.

For the second part, we again note for an integer solution, $d_{ij} = (x_i - x_j)^2 = x_i(1 - x_j) + x_j(1 - x_i)$. Hence, it would suffice to prove $x_j[(1 - x_i) + (1 - x_k)] + (1 - x_j)[x_i + x_k] \geq d_{ik}$. However, this follows by using $x_j[(1 - x_i) + (1 - x_k) - d_{ik}] \geq 0$ and $(1 - x_j)[x_i + x_k - d_{ik}] \geq 0$. For the matrix version, we again use $Y_j, Y_0 - Y_j \in \text{cone}(\text{BS}(G))$ to get

$$\begin{aligned}
2Y_{j,0} - Y_{j,i} - Y_{j,k} &\geq Y_{j,ik} \quad \text{and} \\
(Y_{0,i} - Y_{j,i}) + (Y_{0,k} - Y_{j,k}) &\geq (Y_{0,ik} - Y_{j,ik}).
\end{aligned}$$

Adding the two and replacing every entry $Y_{i,j}$ by $\langle \mathbf{v}_i, \mathbf{v}_j \rangle$ we get $|\mathbf{v}_i - \mathbf{v}_j|^2 + |\mathbf{v}_j - \mathbf{v}_k|^2 \geq |\mathbf{v}_i - \mathbf{v}_k|^2$.

Finding Dense Subgraphs in a Graph

Both the above arguments start with a polytope $\mathcal{P}$ and only consider $N(\mathcal{P})$ and $N_+(\mathcal{P})$. Tighter relaxations, which are still efficient, can be obtained by considering $N^t(\mathcal{P})$ and $N_+^t(\mathcal{P})$, where $t = O(1)$ or even when $t = \omega(1)$ is a slowly growing function of n . However, not many arguments are known which use these, as the sets $N^t(\mathcal{P})$ or $N_+^t(\mathcal{P})$ are often difficult to understand for large t .

Very recently, an application for the densest k -subgraph problem was obtained by Bhaskara *et al.* [14]. Given a graph G and a size parameter k , the problem requires finding a subgraph of k vertices in G , with the maximum number of edges. The previously

best known approximation factor for this problem was $O(n^{0.3159})$ [15,16]. The authors achieve an approximation factor of $O(n^{1/4+\epsilon})$ using $N^{O(1/\epsilon)}(\cdot)$.

Starting with a basic linear program, they strengthen it to a linear program implied by $O(1/\epsilon)$ applications of $N(\cdot)$. The strengthening uses intuition of the solution as a distribution over dense subgraphs. The constraints require that when one conditions $O(1/\epsilon)$ vertices to be in the subgraph, they all must have large expected degree according to the conditional distribution. The full algorithm, however, is significantly more involved and uses various other combinatorial arguments in addition to the LP.

HARDNESS RESULTS FOR OPTIMIZATION PROBLEMS

As discussed in the algorithmic applications, for hard optimization problems, one is often interested in how well the relaxation obtained by $N^t(\mathcal{P})$ approximates the value of the integer program. For a maximization problem, if FRAC denotes the value of a relaxation, and OPT denotes the combinatorial optimum for the optimization problem (i.e., the maximum objective value for an integer solution), then we define the *integrality gap* of the relaxation as the *supremum* of the ratio FRAC/OPT over all instances of the problem. For a minimization problem, we take it to be the inverse ratio. When the integrality gap varies with the

size of the problem, we take the supremum over all instances of size n and express it as a function of n . Note that according to our definition, the integrality gap is always larger than 1, and the closer it is to 1, the better is the performance of the convex relaxation.

From the perspective of complexity theory, one can view the hierarchies of programs defined by the N and N_+ operators as restricted models of computation, with the number of applications of these operators as a resource. This also corresponds naturally to time of computation in this model as optimizing over $N^t(\mathcal{P})$ takes time $n^{O(t)}$. One is then interested in the trade-off between the level of the relaxation in the hierarchy (denoted by t) and the integrality gap of the relaxation. A lower bound in this computational model corresponds to showing that the integrality gap remains large even for the relaxations obtained at very high levels of the hierarchy.

Integrality Gaps for Vertex Cover

Minimum Vertex Cover, the problem of finding the smallest subset of vertices in a graph such that every edge is incident on some vertex in the subset, is perhaps the most studied problem with regard to integrality gaps in the Lovász–Schrijver hierarchy. The study of integrality gaps in this model was initiated by the works of Arora *et al.* [17,18]. They showed that the integrality gap remains at least $2 - \epsilon$ even after $\Omega(\log n)$ levels of the hierarchy. Since the integrality gap can be easily shown to be *at most* 2 even for the starting linear relaxation, this showed that even the use of time $n^{O(\log n)}$ in this model yields no significant improvement. The results were later improved to $3/2$ for $\Omega(\log^2 n)$ levels by Tzourakis [19] and to an optimal lower bound of $2 - \epsilon$ for $\Omega(n)$ levels by Schoenebeck *et al.* [20]. The last result even rules out exponential time algorithms (note that $\Omega(n/\log n)$ levels would correspond to $2^{\Omega(n)}$ time) in this model.

These results work implicitly or explicitly with the “locally conditioned distributions” interpretation discussed in the section titled “The View in Terms of Local Probability Distributions.” One considers sparse random

graphs that have no cycles of size less than $\Omega(\log n)$ so that any subgraph with $O(\log n)$ vertices is a tree. One then starts with a solution that has fractional value $1/2 + \epsilon$ on every vertex. The move of the adversary then corresponds to selecting a vertex where the solution has a fractional value, and fixing it to 1 or 0, that is, conditioning it to be in or out of the vertex cover. As long as the adversary conditions on $O(\log n)$ vertices, the set of conditioned vertices form a tree, restricted to which there is an *actual distribution of vertex covers* with marginal values $1/2 + \epsilon$. Hence, one can use this to produce the required conditional distribution. We remark that this is just an intuition for the proof in Arora *et al.* [18]. The actual proof proceeds by looking at the duals of the linear programs obtained by the LS hierarchy and involves significantly more work. The result in Schoenebeck *et al.* [20] for $\Omega(n)$ levels uses an explicit version of the above intuitive argument together with a more careful use of the sparsity of these graphs.

Integrality gaps for the semidefinite version of this hierarchy have been somewhat harder to prove. It was shown by Goemans and Kleinberg [21] that the integrality gap for the relaxation obtained by one application of N_+ (which is equivalent to the ϑ -function of Lovász) is at least $2 - \epsilon$. The result was strengthened by Charikar [22], who showed that the same gap holds even when the relaxation is augmented with “triangle inequalities” discussed in the section titled “Deriving the SDP Relaxation for Sparsest Cut.” The gap was extended to $\Omega(\sqrt{\log n}/\log \log n)$ levels of the LS_+ hierarchy by Georgiou *et al.* [23]. Interestingly, all these results for LS_+ were proven for the same family of graphs, inspired by a paper of Frankl and Rödl [24]. It is an interesting problem to construct an alternate family which is also an integrality gap instance, or to extend the above results to even $\Omega(\log n)$ levels.

Somewhat incomparable to the above results, integrality gaps of factors $7/6$ for $\Omega(n)$ levels and 1.36 for $n^{\Omega(1)}$ levels of the semidefinite hierarchy were obtained by Schoenebeck *et al.* [25] and Tulsiani [26]. These results also differ from the ones discussed above in that they do not directly

exhibit a family of integrality gap instances for vertex cover. Instead, they start with an integrality gap instance for a constraint satisfaction problem, and proceed by using a reduction from the constraint satisfaction problem to vertex cover.

Results for Constraint Satisfaction Problems

For constraint satisfaction problems with three or more variables in each constraint, strong integrality gaps have been shown for the Lovász–Schrijver semidefinite (and hence also the linear) hierarchy. For these problems, one studies how well convex relaxations approximate the maximum number of constraints that can be satisfied by any assignment to the variables.

Optimal integrality gaps of a factor $2^k/(2^k - 1)$ for K–SAT with $k \geq 5$ and $\Omega(n)$ levels were shown by Buresh-Oppenheim *et al.* [4]. These were later extended to the important remaining case of 3–SAT by Alekhnovich *et al.* [10], who also proved strong lower bounds for approximating minimum vertex cover in hypergraphs. $\Omega(n)$ level integrality gaps for other constraint satisfaction problems also follow from the corresponding results in the Lasserre hierarchy by Schoenebeck [27] and Tulsiani [26]. All these results crucially rely on the ideas of expansion from proof complexity, explained in the section titled “Proof Complexity.”

Results for Other Problems

The performance of the LS hierarchy for the traveling salesman problem was considered by Cook and Dash [8] and by Cheung [28]. A basic LP relaxation for the problem with n cities involves $n(n - 1)/2$ variables and is due to Dantzig, Fulkerson, and Johnson. This relaxation is known to have integrality gap of at least $4/3$. Cook and Dash showed that exactly characterizing the integer optimum requires at least $\lceil n/8 \rceil$ levels of the LS_+ hierarchy. They also exhibited an inequality valid for the integer solutions, such that any LS_+ -derivation of it requires to use at least $2^{n/8}/n^4$ intermediate inequalities. Cheung showed that the integrality gap of the relaxation remains at least $4/3$ after any constant number of levels in the LS hierarchy.

Feige and Krauthgamer [29] studied how well the programs in the Lovász–Schrijver hierarchy do in determining the size of the largest clique in random graphs. Let $G_{n,1/2}$ denote the probabilistic model for generating a random graph by picking each pair of vertices to be an edge independently with probability $1/2$. They were motivated by the the problem of distinguishing a random graph in $G_{n,1/2}$ from the one in which a clique of size k ($\approx \sqrt{n}$) has been planted, which has been suggested as the basis of a cryptographic scheme [30,31].

They showed that the value of the relaxation for maximum clique obtained by N_+^t is almost surely between $\sqrt{n/(2 + \epsilon)^{t+1}}$ and $4\sqrt{n/(2 - \epsilon)^{t+1}}$ for any $\epsilon \in (0, 2)$ and $t = o(\log n)$. Hence, their result shows that one can use $N_+^t(\cdot)$ to find planted cliques of size greater than $4\sqrt{n/(2 - \epsilon)^t}$, but not much smaller than that.

Also, it is well known [32] that the size of the largest clique in a random graph generated according to $G_{n,1/2}$ is almost surely equal to $(2 + o(1))\log_2 n$. It was shown by Lovász and Schrijver [3] that if largest clique in G has size $\omega(G)$, then the value of the relaxation obtained by $t = \omega(G)$ levels of the LS_+ hierarchy is exactly $\omega(G)$. Hence, while the relaxation obtained by $(2 + o(1))\log n$ levels of the hierarchy is almost surely tight, any relaxation obtained by $t = o(\log n)$ levels has a large integrality gap.

PROOF COMPLEXITY

Proof complexity studies the efficiency with which the proof of a given proposition can be derived by a proof system. As discussed earlier, the Lovász–Schrijver hierarchies can be viewed as a proof system, where one starts with a given set of inequalities defining a convex region and derives new ones using the rules in Claim 1. This proof system is known to be at least as powerful as the well-known resolution proof system [33].

Consider a formula φ in conjunctive normal form (CNF), the feasibility of which can be phrased as an integer program in n variables. If $\mathcal{P}$ is the feasible polytope for an LP relaxation of this program, and if φ is unsatisfiable, then we must have $\mathcal{P} \cap \{0, 1\}^n = \emptyset$.

Hence, t applications of $N(\cdot)$ will *prove* that φ is unsatisfiable, if $N^t(\mathcal{P}) = \emptyset$. The smallest t for which $N^t(\mathcal{P})$ (or $N_+^t(\mathcal{P}) = \emptyset$) is known as the N -rank (respectively N_+ -rank) of φ . For proving a lower bound on proof complexity, one is then interested in exhibiting a family of formulas with large (typically $\Omega(n)$) rank.

The techniques developed for proving lower bounds in proof complexity have also been useful in reasoning about general constraint satisfaction problems, and in proving hardness of approximating various optimization problems (using convex relaxations), as discussed in the section titled “Hardness Results for Optimization Problems.”

Expansion and Rank Lower Bounds for Formulas

An important technique for proving lower bounds in proof complexity has been the use of *expansion* in formulas. It was used for proving that if φ is an unsatisfiable 3-CNF formula in n variables, with each set of s clauses (for say $s \leq n/1000$) involving at least (say) $3s/2$ variables, then any proof of the unsatisfiability of φ in the *resolution* proof system must have exponential size [34,35].

Rank lower bounds for LS-proof systems were first proved by Grigoriev *et al.* [36]. Buresh-Oppenheim *et al.* [4] were the first to use expansion arguments in the context of Lovász–Schrijver proof systems. They also proved lower bounds for various optimization problems, which were later extended by Alekhovich *et al.* [10]. Both these papers phrase their arguments in terms of the prover–adversary game discussed in the section titled “The Prover–Adversary Game.”

In their argument, they start with a vector with a fractional value for each variable and prove that the vector is in $N_+^t(\mathcal{P})$ for $t = \Omega(n)$. A move of the adversary in their setting amounts to fixing one of the fractional variables to 1 or 0 (i.e., true or false) and the prover is supposed to provide a fractional assignment consistent with the fixing, which is still in the polytope of feasible solutions. They then obtain the set O by fixing *additional* variables such that the desired fractional vector is a convex combination of

the assignments in O . The additional variables are fixed to maintain the invariant that if one considers the formula restricted only to the variables that have not been fixed to 0 or 1, then the formula is still expanding (in the sense that a set of s clauses will contain at least $3s/2$ unfixed variables). Expansion essentially means that even when $O(n)$ variables are fixed, most clauses still have a large number of unfixed variables, whose value can be modified suitably to satisfy the constraints of the convex program.

Lower Bounds on Size of Proofs

A finer measure than the *rank* of a proof that φ is unsatisfiable is the *size* of the proof. For the Lovász–Schrijver proof system, where one proves unsatisfiability by progressively deriving new inequalities until one gets an obvious contradiction like $0 = 1$, the size may be thought of as the *number* of inequalities that one needs to derive before obtaining a contradiction. A lower bound of t on the rank implies that one will need to use at least $n^{\Omega(t)}$ inequalities, if using *all the inequalities describing* $N^t(\mathcal{P})$. On the other hand, a size lower bound of $n^{\Omega(t)}$ would rule out *any way* of using $n^{O(t)}$ inequalities to prove unsatisfiability. We remark that a more accurate definition would involve the sum of the sizes of the coefficients in all the inequalities used. However, the lower bounds described here also hold for the definition involving number of inequalities.

Dash [37] provided exponential size lower bounds for a version of the Lovász–Schrijver proof systems, which uses an operator weaker than the N and N_+ operators. For “cutting-plane” proof systems based on the cut procedures of Gomory [1] and Chvátal [2], exponential lower bounds on the size of proofs were proved by Pudlák [38]. Kojevnikov and Itsykson [39] later proved exponential lower bounds for “tree-like” proofs in the Lovász–Schrijver proof system, using expansion-based arguments. One says that a given proof is tree-like when each derived inequality is used at most once for another derivation, that is, the derived inequalities form a tree, where the parent is derived using the children.

Pitassi and Segerlind [40] later derived a general trade-off between the rank and size of tree-like proofs in the LS and LS_+ proof systems. They proved that if such a proof has size S and rank t , then one must have $t = \Omega(\sqrt{n \log S})$. Using a rank lower bound of $t = \Omega(n)$, this implies a lower bound of $2^{\Omega(n)}$ on S . However, they also showed that this trade-off did not hold for general (non-tree like) proofs in these proof systems.

Size lower bounds for general proofs in the LS and LS_+ can now be derived via an indirect route, by combining the results of Pitassi and Segerlind with those of Schoenebeck [27]. Although the trade-off of Pitassi and Segerlind did not work for general proofs in the LS-proof system, they showed (extending an argument of Clegg *et al.* [41]) that it *does* hold for general proofs in the proof systems corresponding to the Sherali–Adams and Lasserre hierarchies. This means that an $\Omega(n)$ lower bound on the rank of Lasserre proofs would imply an exponential lower bound on the size in the Lasserre proof system; and hence also on the size of *general* proofs in the LS and LS_+ proof systems (each LS and LS_+ proof can be simulated by a Lasserre proof of the same size). Such rank lower bounds for Lasserre proofs were provided by Schoenebeck [27], thus also proving the required size bounds.

CONCLUSION

The hierarchies of Lovász and Schrijver are an interesting computational model, and can be seen to capture many known approximation algorithms within the first few levels. Perhaps the most interesting problem about these is finding algorithmic applications of programs at the higher levels of these hierarchies. For problems such as sparsest cut and approximate graph coloring, the known lower bounds are far from tight, and it is an intriguing possibility that programs at higher levels can provide a better approximation guarantee for these problems.

In the context of lower bounds, it still remains to settle the integrality gap for the much investigated minimum vertex cover problem in the LS_+ hierarchy. Also, it is interesting to investigate the integrality gaps for

other optimization problems such as sparsest cut and unique games.

Acknowledgments

I thank Sanjeev Arora and Pavel Hrubes for helpful comments and references. I also thank the anonymous referees for suggesting various corrections and improvements to the previous version of this manuscript, and for pointing out that the LP relaxation in Fig. 2 has infinite integrality gap. This work was supported by NSF grant CCF-0832797.

LP DUALITY AND KKT CONDITIONS FOR LP

JENS CLAUSEN
DTU Management,
Technical University of
Denmark, Lyngby,
Denmark

Duality is one of the most fundamental concepts in connection with linear programming (LP) and provides the basis for better understanding of LP models and their results and for algorithm construction in linear and in integer programming. Duality in LP was first introduced by von Neumann in Ref. 1 and can be defined in two ways: The *mathematical definition approach* and the *multiplier approach*. Duality can furthermore be motivated in an economical setting. In most textbooks, as for example [2–4], duality is introduced combining the first and third of these approaches.

Here, we first define duality using the multiplier approach for a specific set of LPs. Although not used explicitly to define duality, the approach is implicitly described in Ref. 5 under the heading Lagrangean relaxation. A similar approach is used in Ref. 6, and for non-linear programming (NLP) and integer programming in Refs 7 and 8.

Then we state both the Weak and the Strong Duality Theorems formulated first in Ref. 9. The mathematical definition approach is used to define the dual to any given LP and we show the natural correspondence with the multiplier approach.

The Complementary Slackness Conditions for optimality of a pair of solutions to a primal LP and its corresponding dual are stated and proved, and finally the relation between these and the KKT conditions for optimality, known from NLP, is demonstrated, thus showing the intimate relationship between duality in LP and KKT-conditions for NLPs.

DERIVING THE DUAL PROBLEM

The standard form of an LP, which is commonly used when introducing the Simplex method for solving LP problems, is a problem with n nonnegative variables and m equality constraints:

$$\begin{array}{ll} \min & cx \\ & Ax = b \quad (P) \\ & x \geq 0. \end{array}$$

Here, c is an $1 \times n$ matrix, A is an $m \times n$ matrix, b is an $m \times 1$ matrix of reals, and x is an $n \times 1$ vector of real variables. This form is the outset for our presentation of duality.

A very common and general approach to problem solution is to transform the problem at hand to a similar problem, which is possibly easier to solve. In the LP case, this raises the question of which LPs are easily solvable. The answer is immediate: an LP consisting only of an objective function and nonnegativity constraints on the variables. If any coefficient in the objective function is negative, the solution is unbounded from below (in the following termed *equal to* $-\infty$) with the corresponding variable unbounded (termed *equal to* ∞) and all other variables equal to 0. Otherwise, it is 0 with all variables equal to 0.

Transforming our initial problem by deleting all constraints does not make much sense, that is, the transformed problem is simply too far from the original one. We therefore reintroduce each constraint in the objective function through a term, which consists of the difference between the right-hand side and the left-hand side of the constraint, $b_i - A_i x$, multiplied with a multiplier y_i . We hence introduce m multipliers $y_1, \dots, y_m$ —one for each constraint of the original problem.

Regardless of the sign of these multipliers, the optimal value of the transformed problem now constitutes a lower bound for the value of the original problem. For any feasible solution to the original problem, the new terms in the objective function vanish (since

the constraints of the original problem are equality constraints) and the original value results. Thus the minimum is to be found over a range including all values of feasible solutions and most likely many other values; hence, the minimum is less than or equal to the minimum for the original LP.

Since we are interested in information about our original problem, a natural question is: Which multipliers provide the best possible lower bound, and how is this bound related to the optimal value of the original problem? The answer can be found by solving the following maximization problem:

$$\max_{y \in \mathcal{R}^m} \left\{ \min_{x \in \mathcal{R}_+^n} \{ cx + y(b - Ax) \} \right\}$$

In the inner minimization problem, the y 's are constants and hence yb is a constant. Rearranging the terms in the objective function, we arrive at an LP problem with no constraints but the nonnegativity of the variables:

$$\max_{y \in \mathcal{R}^m} \left\{ \min_{x \in \mathcal{R}_+^n} \{ (c - yA)x + yb \} \right\}$$

If any coefficient $(c - yA)_j$ in the objective function is less than 0, we know that the lower bound becomes $-\infty$, which provides no new knowledge. In the process of deriving the best lower bound, we therefore require that

$$\forall j \in 1, \dots, m : (c - yA)_j \geq 0 \Leftrightarrow yA_j \leq c_j$$

Since we have imposed no bounds on our multipliers, the problem of finding the best multipliers providing the tightest lower bound for our original problem becomes

$$\begin{array}{ll} \max & yb \\ & yA \leq c \quad (DP) \\ & y \text{ free} \end{array}$$

As shown in the following section, the best lower bound surprisingly turns out to equal the optimal value of the primal objective function. The step in the process, where the constraints are included in the objective function, is called a *relaxation*—the constraints of the transformed problem are weaker and

the objective function is pointwise below the original one for all feasible solutions.

The original problem is termed the *primal* LP problem as indicated by (P) and the problem of finding the best lower bound is termed the *dual* LP problem as indicated by (DP) . Together, these are called a *pair of primal and dual* LP problems. Note the following crucial points: For each constraint in the primal problem, there is a variable in the dual problem, and for each variable in the primal problem, there is a constraint in the dual. When the primal problem is a minimization problem, the dual is a maximization problem.

We further illustrate the process and the interplay between relational operators of constraints respective sign constraints for variables of the primal problem and sign constraints respective relational operators of constraints in the dual problem by summarizing the process for a maximization problem in non-negative variables with less than or equal constraints:

$$\begin{array}{ll} \max & cx \\ & Ax \leq b \\ & x \geq 0 \end{array} \quad \mapsto \quad \begin{array}{ll} \min_{y \in \mathcal{R}_+^m} & \left\{ \max_{x \in \mathcal{R}_+^n} \{ cx + y(b - Ax) \} \right\} \\ \min_{y \in \mathcal{R}_+^m} & \left\{ \max_{x \in \mathcal{R}_+^n} \{ (c - yA)x + yb \} \right\} \end{array} \quad \mapsto \quad \begin{array}{ll} \min & yb \\ & yA \geq c \\ & y \geq 0. \end{array}$$

Since the primal problem is one of maximization, we search for a tightest upper bound. To provide an upper bound, the new objective function has to be pointwise larger than or equal to the original one for each feasible solution; hence, each multiplier must be nonnegative. The outer objective function is to be minimized, and each coefficient in the inner maximization problem must be nonpositive in order to provide a bounded solution to this.

Before we address the general construction of a dual problem from a given primal, we state the Weak and the Strong Duality theorem for the particular case just developed.

THE DUALITY THEOREMS

Theorem 1 [The Weak Duality Theorem].

Consider a given pair of primal and dual LP problems $\min\{cx \mid Ax = b, x \geq 0\}$ and $\max\{yb \mid yA \leq c, y \text{ free}\}$. The value yb of any dual feasible solution y is less than or equal to the value cx of any primal feasible solution x .

We have already proven the theorem during the construction process by noting that for any given set of multipliers, the value of the transformed problem is a lower bound for the value of the primal problem.

The Weak Duality Theorem shows that if the primal problem is feasible and unbounded, the dual problem must be infeasible and vice versa. However, this leaves open the possibility that both the primal and dual problems are infeasible, and such examples do exist.

Theorem 2 [The Strong Duality Theorem].

If feasible solutions to both the primal problem $\min\{cx \mid Ax = b, x \geq 0\}$ and the dual problem $\max\{yb \mid yA \leq c, y \text{ free}\}$ exist, then each of these has an optimum solution and the values of these solutions are equal.

Our proof of the Duality Theorem proceeds in the traditional way. We identify a set of dual variables—multipliers—which satisfy the dual constraints and give a dual objective function value equal to the optimal primal value.

Assuming that P and DP have feasible solutions implies that P can be neither infeasible nor unbounded. Hence an optimal basis B and a corresponding optimal basic solution x_B for P exists. The coefficient matrix A , the vector of objective coefficients c , and the vector of variables x can be rearranged and denoted $A = BN$, $c = (c_B c_N)$, and $x = (x_B x_N)$. With this notation, the optimal basic solution take the values $x_B = B^{-1}b$, $x_N = 0$. The vector $y_B = c_B B^{-1}$ is called the *dual solution* or the set of *simplex multipliers* corresponding to B . If the reduced costs of the simplex tableau are calculated using y_B as multipliers:

$$\bar{c} = c - y_B A,$$

then as required by the Simplex method, $\bar{c}_j$ equals 0 for all basic variables and $\bar{c}_j$ is non-negative for all nonbasic variables. Hence,

$$y_B A \leq c$$

holds, showing that y_B is a feasible dual solution. The value of this solution is $c_B B^{-1}b$, which is exactly the same as the primal objective value: $(c_B c_N)(x_B x_N) = c_B B^{-1}b$.

The dual solution y_B corresponding to the optimal basis B is often termed the vector of *shadow prices*. The terminology stems from problems, in which one wants to maximize the profit of selling a set of products produced from a set of raw materials by, for example, blending. This leads to a maximization problem in nonnegative variables with constraints being of the type “less than or equal,” each constraint limiting the use of some raw materials by the available amount. The optimal value of the dual variable for such a constraint indicates the break-even price for the corresponding raw material, that is, the price at which the cost of buying more raw material equals the increase in profit resulting from using the extra raw material. Hence, if not all the available units are used, the corresponding dual optimal value must be 0.

GENERAL DEFINITION OF DUALITY

Consider now the situation, where a general LP with m constraints and n variables is given:

$$\begin{array}{llll} \text{min/max} & cx & & \\ & Ax & \geq, =, \leq & b \\ & x & \geq, \leq, \text{free} & 0. \end{array}$$

The objective function may be minimize or maximize, for each constraint the primal relational operator may be $\leq$, $\geq$, or $=$, and for each variable, the primal sign constraint may be ≥ 0 , ≤ 0 , or *free* (indicating no constraint).

The dual problem is then

$$\begin{array}{llll} \text{max/min} & yb & & \\ & yA & \geq, =, \leq & c \\ & y & \geq, \leq, \text{free} & 0. \end{array}$$

Table 1. The Interplay Between Relational Operators in the Primal LP and Sign Constraints of the Variables in the Dual LP

Primal: Min		Dual: Max	
(a) i th constraint	$\geq$	i th variable	≥ 0
(b) i th constraint	$\leq$	i th variable	≤ 0
(c) i th constraint	$=$	i th variable	free
(d) j th variable	≥ 0	j th constraint	$\leq$
(e) j th variable	≤ 0	j th constraint	$\geq$
(f) j th variable	free	j th constraint	$=$

Primal: Max		Dual: Min	
(a) i th constraint	$\geq$	i th variable	≤ 0
(b) i th constraint	$\leq$	i th variable	≥ 0
(c) i th constraint	$=$	i th variable	free
(d) j th variable	≥ 0	j th constraint	$\geq$
(e) j th variable	≤ 0	j th constraint	$\leq$
(f) j th variable	free	j th constraint	$=$

The interplay between primal relational operators and the corresponding dual sign constraints and vice versa can be derived by “best bound” arguments as in the section titled “Deriving the Dual Problem” and is given in Table 1.

In the general case, the Weak Duality Theorem follows from relaxation arguments exactly, as previously shown. The Strong Duality Theorem is slightly more complicated to prove - the given problem is transformed to standard form using slack and/or surplus variables, and it is demonstrated that these two equivalent problems have the same dual problem. The theorem now follows from the construction applied for the standard form.

OPTIMALITY CONDITIONS FOR PAIRS OF LPs—COMPLEMENTARY SLACKNESS

When developing iterative solution algorithms for the optimization problems, it is crucial to identify optimality conditions—such conditions enable an algorithm to stop iterating when optimality is achieved. One obvious condition when solving an LP is that a primal feasible solution x and a dual feasible solution y with equal values are identified. This is a consequence of

the Weak Duality Theorem. The *Complementary Slackness Conditions*—termed the *CS-conditions*—constitute another set of optimality conditions for a given pair of dual LPs. We first formulate these for a specific type of pair of dual problems.

Theorem 3. *Consider a pair of dual LP-problems, P , and DP :*

$$\begin{array}{ll} \max & cx \\ & Ax \leq b \quad (P) \\ & x \geq 0 \end{array} \quad \begin{array}{ll} \min & yb \\ & yA \geq c \quad (DP) \\ & y \geq 0 \end{array}$$

and a pair $\bar{x}, \bar{y}$ of feasible solutions to P and DP , respectively. $\bar{x}$ and $\bar{y}$ are optimal solutions to P and DP , respectively, if and only if, they satisfy the complementary slackness conditions:

$$\begin{aligned} \forall i \in \{1, \dots, m\} : \bar{y}_i(b_i - A_i\bar{x}) &= 0 \\ \forall j \in \{1, \dots, n\} : (\bar{y}A_j - c_j)\bar{x}_j &= 0 \end{aligned}$$

The terms $(b_i - A_i\bar{x})$ and $(\bar{y}A_j - c_j)$ are called the i th primal slack and j th dual slack, respectively.

Before commenting on the general form of the CS-conditions, we prove the theorem. Both primal and dual variables are non-negative. Furthermore, for feasible solutions, $b_i - A_i x \geq 0$ and $yA_j - c_j \geq 0$ hold. Therefore, each term $y_i(b_i - A_i x)$ and $(yA_j - c_j)x_j$ is nonnegative, and the CS-conditions can be stated in compact notation as

$$\bar{y}(b - A\bar{x}) = 0 \wedge (\bar{y}A - c)\bar{x} = 0.$$

Suppose that a pair $\bar{x}, \bar{y}$ of feasible solutions satisfy the CS-conditions. Now:

$$c\bar{x} = (\bar{y}A)\bar{x} = \bar{y}(A\bar{x}) = \bar{y}b,$$

where the first and third equality follow from the CS-conditions. Hence $\bar{x}$ and $\bar{y}$ are feasible

primal and dual solutions with the same value, and by the Weak Duality Theorem, both must be optimal.

Suppose now $\bar{x}$ and $\bar{y}$ are feasible optimal solutions implying that $c\bar{x} = \bar{y}b$. Thus,

$$c\bar{x} \leq (\bar{y}A)\bar{x} = \bar{y}(A\bar{x}) \leq \bar{y}b = c\bar{x}.$$

Here, the first inequality is due to the feasibility of $\bar{y}$ and the nonnegativity of $\bar{x}$, the second to the feasibility of $\bar{x}$ and nonnegativity of $\bar{y}$, and the last equation to the optimality of both. Hence, equality must hold throughout the expression implying that the CS-conditions are satisfied.

The CS-conditions can be shown to be necessary and sufficient optimality conditions for a pair of primal and dual feasible solutions, no matter which form the relational operators and sign constraints take in the problems at hand. Note specifically the situation when the primal problem is in standard form: minimization of a problem in nonnegative variables and with equality constraints. In this case, the CS-conditions

$$\forall i \in \{1, \dots, m\} : \bar{y}_i(b_i - A_i\bar{x}) = 0,$$

are vacuously fulfilled for a pair of feasible solutions $\bar{x}, \bar{y}$. Noting that for a set of basic feasible solutions, the reduced costs are calculated as $\bar{c} = c - c_B B^{-1}A$, the remaining CS-conditions can be formulated as

$$\forall j \in \{1, \dots, n\} : \bar{c}_j x_j = 0$$

Since only basic variables are allowed to take positive values in a basic solution, and all nonbasic reduced costs are 0, these CS-conditions are also satisfied by any basic solution generated when the problem at hand is solved iteratively by the simplex method. The ratio test ensures that the basic solution of each iteration is feasible. The iterations stop when all reduced costs are nonnegative, which is equivalent to that $y_B = c_B B^{-1}$ constitute a dual feasible solution. Hence the iterations maintain primal feasibility of the basic solution and the CS-conditions, and

strive for feasibility of the dual solution corresponding to the basis.

KKT CONDITIONS FOR AN LP

The KKT conditions [9] are optimality conditions for NLPs. Since LPs are special cases of NLPs these conditions apply also in the linear case. However, as will become clear, the KKT-conditions for optimality are in the linear case the CS-conditions just stated. We start by stating the conditions, and then we interpret these in a linear setting.

We consider the following problem in n variables with m inequality and p equality constraints. All functions are assumed to be differentiable:

$$\begin{aligned} \max \quad & f(x) \\ g(x) \quad & \leq b \\ h(x) \quad & = c \\ x \quad & \in R^n \end{aligned}$$

A given $x^o \in R^n$ satisfies the KKT-conditions if and only if:

1. x^o is feasible, and
2. there exist $\lambda_j, j = 1, \dots, m$ and $\mu_k, k = 1, \dots, p$ such that

$$\begin{aligned} \nabla f(x^o) &= \sum_{j=1}^m \lambda_j \nabla g_j(x^o) + \sum_{k=1}^p \mu_k \nabla h_k(x^o) \\ \lambda_j(b_j - g_j(x^o)) &= 0, \quad j = 1, \dots, m \\ \lambda_j &\geq 0, \quad j = 1, \dots, m. \end{aligned}$$

The operator ∇ indicates partial derivation $\nabla g_j(x) = \partial(g_j(x))/\partial x_1, \dots, \partial(g_j(x))/\partial x_i, \dots, \partial(g_j(x))/\partial x_n$. Condition (2) can be rephrased as follows: There exist vectors $\lambda \in R^m$ and $\mu \in R^p$ such that

$$\begin{aligned} \nabla f(x^o) &= \lambda \nabla g(x^o) + \mu \nabla h(x^o) \\ \lambda(b - g(x^o)) &= 0 \\ \lambda &\geq 0. \end{aligned}$$

If the functions $f(\cdot)$, $g(\cdot)$, and $h(\cdot)$ are all linear, we may consider the problem at hand as the primal problem in a pair of dual problems and state it together with its dual

$$\begin{array}{llll}
\max & cx & \min & \lambda b_1 + \mu b_2 \\
& A_1 x & \leq & b_1 \\
(P) & A_2 x & = & b_2 \\
& x & \text{free} & \\
\end{array}
\quad
\begin{array}{ll}
(\lambda, \mu) \begin{pmatrix} A_1 \\ A_2 \end{pmatrix} & = c \\
\lambda & \geq 0 \\
\mu & \text{free}
\end{array}
\quad (DP)$$

Writing out the KKT-conditions for a given $x^o \in R^n$ using that the j th partial derivative of a linear function $a_{i1}x_1 + a_{i2}x_2 + \dots + a_{in}x_n$ is just a_{ij} , these state that

1. x^o is feasible, and
2. there exist $\lambda_j, j = 1, \dots, m$ and $\mu_k, k = 1, \dots, p$ such that

$$\begin{aligned}
c &= \sum_{j=1}^m \lambda_j A_{1j} + \sum_{k=1}^p \mu_k A_{2k}. \\
\lambda_j (b_j - A_{1j} x^o) &= 0, \quad j = 1, \dots, m \\
\lambda_j &\geq 0, \quad j = 1, \dots, m.
\end{aligned}$$

If we rephrase (2), we get that there exist vectors $\lambda \in R^m$ and $\mu \in R^p$ such that

$$\begin{aligned}
c &= \lambda A_1 + \mu A_2 \\
\lambda (b - A_1 x^o) &= 0 \\
\lambda &\geq 0.
\end{aligned}$$

However, considering x^o as a primal solution and λ, μ as a dual solution, condition (1) states primal feasibility, the first part and third part of condition (2) dual feasibility, and the second part of condition (2) that x^o, λ , and μ satisfy the CS-conditions. Note that both the CS-conditions regarding the primal constraints $A_2 x = b_2$ and the dual constraints $c = \lambda A_1 + \mu A_2$ are vacuously fulfilled—all feasible solutions leave no slack in any of these constraints.

Hence, the statement for NPLs that “under certain assumptions on the functions $f(\cdot), g(\cdot)$, and $h(\cdot)$, the KKT-conditions are both necessary and sufficient for optimality of a point $x^o \in R^n$ ” in the linear case reduces to “a primal feasible solution is optimal if and only if a dual feasible solution exists

such that the pair of solutions satisfy the CS-conditions.”

OPTIMALITY CONDITIONS REVISITED - GEOMETRY

Through an example, we now illustrate the CS- and KKT-conditions for LP optimality from a geometric point of view. Consider the following LP-problem in two nonnegative variables:

$$\begin{aligned}
\max & 7x_1 + 11x_2 \\
& -2x_1 + x_2 \leq 1 \\
& x_1 + x_2 \leq 7 \\
& x_2 \leq 2.5 \\
& x_1, x_2 \geq 0
\end{aligned}$$

The feasible region is shown in Fig. 1, and the optimal solution is $A = (x_1, x_2) = (9/2, 5/2)$.

An alternative formulation of the problem is as a maximization problem with only $\geq$ -constraints and free variables:

$$\begin{aligned}
\max & 7x_1 + 11x_2 \\
& 2x_1 - x_2 \geq -1 \\
& -x_1 - x_2 \geq -7 \\
& -x_2 \geq -2.5 \\
& x_1 \geq 0 \\
& x_2 \geq 0 \\
& x_1, x_2 \text{ free}
\end{aligned}$$

The general form with m constraints and n variables is

$$\begin{array}{ll}
\max & cx \\
& Ax \geq b \\
& x \text{ free}
\end{array}$$

Figure 1. The feasible region and optimal solution for an LP in 2 dimensions.

with the dual problem

$$\begin{aligned} \min \quad & yb \\ \text{subject to} \quad & yA = c \\ & y \leq 0 \end{aligned}$$

Hence the dual problem to the alternative formulation is

$$\begin{aligned} \min \quad & -y_1 - 7y_2 - 2.5y_3 + 0y_4 + 0y_5 \\ \text{subject to} \quad & 2y_1 - y_2 + y_4 = 7 \\ & -y_1 - y_2 - y_3 + y_5 = 11 \\ & y_1, y_2, \dots, y_5 \text{ free} \end{aligned}$$

A given x^o is now according to the KKT-conditions an optimal solution *if and only if*

1. x^o is a feasible solution to P, and
2. there exists a vector y^o satisfying the following:

$$\begin{aligned} y^o A &= c & (1) \\ y^o (b - Ax^o) &= 0 & (2) \\ y^o &\leq 0 & (3) \end{aligned}$$

Considering (1) and (3), these conditions indicate that y^o is feasible for the dual problem, and (2) is just CS-conditions for x^o, y^o .

Geometrically, the vector c is the *gradient* of the objective function cx , that is, that direction for a move in R^n , for which the objective function *increases* most rapidly. The feasible region $S = \{x | Ax \geq b\}$ for the problem is defined by the functions $a_{11}x_1 + \dots + a_{1n}x_n - b_1, \dots, a_{m1}x_1 + \dots + a_{mn}x_n - b_m$, which must

Figure 2. The KKT-optimality conditions for an LP in two dimensions.

all have values greater than or equal to 0 in a given x for this to be feasible. The gradients $(a_{11}, \dots, a_{1n}), \dots, (a_{m1}, \dots, a_{mn})$ for these functions viewed as vectors are directed *into* the feasible region S ; see Fig. 2. Condition (1) and (3) now state that at an optimal point of S —an extreme point Q —the gradient of the objective function must be a *nonpositive linear combination* of the gradients of the constraints, while condition (2) states that only *binding* constraint may have nonzero coefficients in this linear combination. The situation for the example with $Q = A = (9/2, 5/2)$ is illustrated in Fig. 2. Intuitively, if just one of the gradients of the linear combination has a positive coefficient, the current solution is not optimal. This is demonstrated by the existence of a positive reduced cost.

One interesting final point to mention is that the KKT-conditions may be satisfied also by optimal points, which are not extreme points of the feasible region. Consider, for example, the previous example but now with the objective function $x_1 + x_2$. In this case, all points on the line connecting $(9/2, 5/2)$ and $(7, 0)$ are optimal, for example, $B = (5, 2)$. The only binding constraint for this point is $-x_1 - x_2 + 7 \geq 0$. Choosing the dual variables as $(y_1, y_2, y_3, y_4, y_5) = (0, -1, 0, 0, 0)$, the optimality of $(5, 2)$ is verified by the KKT-conditions as well as the CS-conditions.

SUMMARY

We have presented the theory of duality in LP in a rather untraditional setting with the goal of providing a thorough understanding of the origin of the dual problem for any

given primal problem. With this approach, the use of relaxation and duality in integer programming algorithms such as Branch and Bound and the general KKT-conditions for optimality in NLP become natural extensions of the LP duality theory.

MACBETH (MEASURING ATTRACTIVENESS BY A CATEGORICAL BASED EVALUATION TECHNIQUE)

CARLOS A BANA E COSTA
Centre for Management Studies of
IST, Technical University of
Lisbon, Lisbon, Portugal

JEAN-MARIE DE CORTE
JEAN-CLAUDE VANSNICK

University of Mons, Mons, Belgium

BACKGROUND OF MACBETH

Measuring the attractiveness of options through a category-based evaluation technique is the goal of MACBETH. Its key distinction from other value-measurement procedures, such as numerical direct rating, is that MACBETH uses qualitative judgments of differences in attractiveness in order to generate value scores for the options.

To facilitate comparison of options, two at a time, MACBETH introduces seven qualitative categories of difference in attractiveness: Is there no difference (indifference), or is the difference very weak, weak, moderate, strong, very strong, or extreme? Judgmental disagreement or hesitation between two or more consecutive categories, except indifference, is also allowed. MACBETH relies on such a pairwise comparison questioning mode. Each time that a qualitative judgment is elicited, the consistency of all the judgments thereto made by the respondent is verified and suggestions are offered to resolve inconsistencies if they arise, as detailed in the section titled “Dealing with Inconsistency while Eliciting Qualitative Judgments.”

MACBETH then derives scores for the options from the consistent set of judgments. These scores constitute the basic MACBETH numerical scale (v), which the respondent should subsequently validate (see the section titled “The Basic MACBETH Scale”). To validate the scale, the respondent should compare the sizes of the intervals between the

proposed scores and adjust them if necessary, one at a time within a range compatible with the judgments elicited. If further adjustment is needed, the respondent may even revise judgments previously provided. The aim of this process is to quantify the relative attractiveness of the options on an interval measurement scale (see the section titled “Constructing an Interval Scale”).

In a multiple criteria evaluation context, scoring the options on an interval scale within each criterion is important because it permits one to meaningfully take a weighted average of each option's scores on the criteria. This overall score measures the relative attractiveness of the option across all the criteria. The weights of the criteria can also be derived by applying the MACBETH procedure to a set of reference, hypothetical, options.

MACBETH uses mathematical programming to test consistency, find suggestions to resolve inconsistencies if they arise, derive the basic MACBETH scale for a set of consistent judgments, and find the range within which each proposed score can be adjusted. All technical details are given in the article On the Mathematical Foundations of MACBETH [1], which integrates and updates all developments since the initial formulation in Ref. 2. The MACBETH procedure is implemented in the M-MACBETH software application (available at www.m-macbeth.com), which also includes functionalities to help structure criteria and to interactively analyze the sensitivity and robustness of the model's results in the face of several sources of uncertainty (as detailed in Refs 3 and 4).

DEALING WITH INCONSISTENCY WHILE ELICITING QUALITATIVE JUDGMENTS

Suppose that one wants to apply MACBETH to help in evaluating four options A, B, C, D, on a given criterion. In the process of pairwise comparing the options, assume the respondent started by judging A to be weakly more attractive than B, then B to be more attractive than C but hesitated between a very weak or a weak difference in attractiveness, and considered B to be moderately more

	A	B	C	D
A	No	Weak	?	?
B		No	Vweak-weak	Moderate
C	?		No	Moderate
D	?			No

(a)

Figure 1. Consistent (a) and inconsistent (b) sets of judgments. It is of note that “?” in a entry means that there is no information about the difference in attractiveness between the corresponding two options; “vweak-weak” is an abbreviation of “very weak or weak” difference in attractiveness.

	A	B	C	D
A	No	Weak	Strong	?
B		No	Vweak-weak	Moderate
C			No	Moderate
D	?			No

(b)

attractive than D, and considered C also to be moderately more attractive than D. These judgments were used to populate the upper triangular part of the matrix in Fig. 1a. As each judgment was entered into the matrix, its consistency with the judgments already inserted into the matrix was checked.

In MACBETH, consistency means that, from a set of elicited judgments, it is possible to derive scores for the options such that equally attractive options get the same score, an option more attractive than another one gets a greater score, and if the difference in attractiveness between two options (strong, for example) is greater than the difference in attractiveness between two other options

(moderate, for example), then the difference between the scores for the first two options should be greater than the difference between the scores for the other two.

The set of MACBETH judgments in the matrix of Fig. 1a is consistent. However, when the respondent next judged A to be strongly more attractive than C, the set of judgments elicited (Fig. 1b) became inconsistent. This is because the judgments elicited impose that $v(C) - v(D) > v(A) - v(B)$ and $v(A) - v(C) > v(B) - v(D)$, which lead, by summation, to an impossibility: $v(A) - v(D) > v(A) - v(D)$. This conflict between qualitative judgments is easy to see in the graph of Fig. 2: indeed, the length of path A–C–D should be equal to the length of path A–B–D, but this is impossible with the judgments elicited.

Faced with an inconsistent matrix of judgments, the M-MACBETH software recognizes the problem and is able to identify the minimum number of judgments that should be modified to achieve consistency; moreover, it gives users suggestions for such modifications. In the example, consistency is achieved if one of the four suggestions shown in Fig. 3 is accepted: move (A, B) or (B, D)

Figure 2. Graph of inconsistent judgments.

	A	B	C	D
A	No	↑ Weak	↓ Strong	?
B		No	Vweak-weak	↑ Moderate
C			No	↓ Moderate
D	?			No

Figure 3. MACBETH suggestions to resolve inconsistency.

up one category, or (A, C) or (C, D) down one category.

Suppose that when alerted to the inconsistency and presented with the suggestions to resolve it, the respondent decided to revise the judgment between A and C from strong to moderate. Finally, the last judgment was elicited, extreme difference of attractiveness between A and D, completing the consistent matrix of judgments of Fig. 4.

The number of qualitative judgments elicited can range from a maximum of $n(n-1)/2$ (6 judgments for $n=4$ options, as in Fig. 4), when all pairwise comparisons are made, to a minimum acceptable number of $n-1$ judgments, as when comparing only one option with all of the other $n-1$ or each of two consecutive options (as done in Ref. 5). However, it is recommended that some additional judgments be elicited. Belton and Stewart [6, p. 173] present an example in which $2n-3$ judgments are made, filling in only the two first diagonals as in Fig. 1b, whereas Bana e Costa and Chagas [7] fill in the border of the upper triangular portion of the matrix, for a total of $3(n-2)$ pairwise comparisons.

THE BASIC MACBETH SCALE

Let X be a finite set of $n > 2$ (actual or hypothetical) options, among which x^+ and x^- are such that x^+ is at least as attractive as any other option of X and x^- is at most as attractive as any other option of X . Assume that a set of pairwise comparison judgments has been expressed by a respondent in terms of the seven MACBETH categories ($C_k, k = 0, \dots, 6$) of difference in attractiveness: “null” (C_0), “very weak” (C_1), “weak” (C_2), “moderate” (C_3), “strong” (C_4), “very strong” (C_5), and “extreme” (C_6). A judgment between two options x and y of X such that x is at least as attractive as y will be denoted by $(x, y) \in C_k (k = 0, \dots, 6)$ when the difference in attractiveness between x and y is expressed by the single category C_k and $(x, y) \in C_i \cup \dots \cup C_s (i, s = 1, \dots, 6 \text{ with } i < s)$, when judgmental disagreement or hesitation among the categories C_i to C_s is expressed.

The basic MACBETH scale corresponding to the set of judgments expressed by the respondent can be obtained by solving the following linear programming problem, where

	A	B	C	D
A	No	Weak	Moderate	Extreme
B		No	Vweak-weak	Moderate
C			No	Moderate
D				No

Figure 4. MACBETH matrix of judgments of difference in attractiveness.

Figure 5. Basic and anchored MACBETH scales.

$v(x)$ is the score assigned to option x :

$$\text{Min}[v(x^+) - v(x^-)]$$

s. t.

- (1) $v(x^-) = 0$ (arbitrary assignment),
- (2) $\forall(x, y) \in C_0 : v(x) - v(y) = 0$,
- (3) $\forall(x, y) \in C_i \cup \dots \cup C_s$
with $i, s \in \{1, 2, 3, 4, 5, 6\}$
and $i \leq s : v(x) - v(y) \geq i$,
- (4) $\forall(x, y) \in C_i \cup \dots \cup C_s$ and
 $\forall(w, z) \in C_{i'} \cup \dots \cup C_{s'}$
with $i, s, i', s' \in \{1, 2, 3, 4, 5, 6\}, i \leq s, i' \leq s'$,
and $i > s' :$
 $v(x) - v(y) \geq v(w) - v(z) + i - s'$.

When this linear program is infeasible, the set of judgments is inconsistent. When it is feasible, the optimal solution may not be unique. If multiple solutions exist, there is more than one possible score for at least one option $x \in X \setminus \{x^-, x^+\}$, in which case their average is taken to ensure the uniqueness of the basic MACBETH scale (see details in Ref. 1).

The basic MACBETH scale for the set of judgments in Fig. 4 is $v(A) = 8, v(B) =$

$5, v(C) = 4$, and $v(D) = 0$. Note that this scale is equivalent to the scale anchored on $v(x^+) = 100$ and $v(x^-) = 0$, which is displayed graphically by default in the M-MACBETH software (see Fig. 5).

It is worthwhile to point out that the above linear program corresponds to the LP-MACBETH presented in Ref. 1. If none of the judgments are expressed by more than one category (i.e., there is no hesitation between two categories for any of the judgments elicited), the problem takes the form presented in Ref. 8 by writing constraints (3) and (4) above simply as $\forall(x, y) \in C_k$ and $\forall(w, z) \in C_{k'}$ with $k, k' \in \{0, 1, 2, 3, 4, 5, 6\}$ and $k > k'$:

$$v(x) - v(y) \geq v(w) - v(z) + k - k'.$$

CONSTRUCTING AN INTERVAL SCALE

Deriving a MACBETH scale from a consistent set of judgments is not an end in itself but a path in the learning process of measuring attractiveness in an interval scale: relative differences of scores should reflect the relative differences in attractiveness that the respondent feels between the respective options; thus, the ratio between any two positive differences of scores should represent the proportion between the respective differences in attractiveness. This is facilitated by inviting the respondent to observe the scale axis and compare score intervals. For example, one can observe in Fig. 5 that the intervals between A and C and C and D are equal and validate if the respondent feels that the difference in attractiveness between A and C is the same as that between C and D. Similarly, one can validate if the difference of attractiveness between A and B is three times greater than that between B and C. If it is found that distances between options in the scale axis do not adequately represent the respective differences in attractiveness, then at least one score should be adjusted.

As exemplified in Fig. 6, when the user selects an option in the axis, the software shows the range within which the respondent can adjust the score of the selected

Figure 6. Range of variation of a score.

option, keeping the scores of the remaining options unchanged, without violating the consistency of the matrix of judgments. For example, as shown in Fig. 7, the lower bound 3.01 for the score of C is due to the weak and moderate judgments of difference in attractiveness between A and B and between C and D, respectively, implying that $v(C) - v(D) > v(A) - v(B)$, and so, with the fixed scores $v(A) = 8$, $v(B) = 5$, and $v(D) = 0$, one must have $v(C) > 3$. Obviously, if the respondent feels that the intervals between A and B and between C and D should be equal,

	A	B	C	D	Current scale
A	No 0.00	Weak 3.00	Moderate 4.99	Extreme 8.00	8.00
B		No 0.00	Vweak-weak 1.99	Moderate 5.00	5.00
C			No 0.00	Moderate 3.01	3.01
D				No 0.00	0.00

Figure 7. Judgments defining a bound for a score.

the set of judgments can be revised and the process restarted until the respondent feels that the final scores are such that relative differences between them reflect the respective relative differences in attractiveness.

CONCLUSION

One of the most crucial and difficult stages in making multicriteria evaluations is expressing clearly and consistently one's judgments about the relative value or attractiveness of options. When called in to organizations to facilitate this process, decision analysts can use numerical or nonnumerical value-elicitation techniques, such as the numerically based direct rating technique [9] or *measuring attractiveness by a categorical-based evaluation technique (MACBETH)*.

As described, the MACBETH value-elicitation procedure is composed of an input stage aimed at eliciting a consistent set of qualitative (non-numerical) pairwise comparison judgments of difference in attractiveness, and an output stage aimed at constructing an interval value scale from the set of judgments, which numerically measures the relative attractiveness of options for the person or group that made the judgments.

A wide variety of real-world cases using MACBETH and its software is referred to in

Ref. 1; some of them are described in the operational research and management science literature, such as the multicriteria socio-technical processes, combining social aspects of decision conferencing [10] with the technical components of MACBETH, to help groups evaluate bids in international call for tenders [11,12], prioritize public investments, [8,13,14] or allocate resources [15].

MAINTENANCE MANAGEMENT

KIT-NAM FRANCIS LEUNG
Department of Management Sciences,
City University of Hong Kong,
Kowloon Tong, Hong Kong

PRELUDE

The mathematical theory of reliability has grown out of the demands of modern technology, and particularly the demand for effective maintenance and use of management science (MS), also called *operational/operations research* (OR), as is evident from complex military systems experience in World War II [1]. One of the first areas of reliability to be approached with any mathematical sophistication was the area of machine maintenance [2]. The techniques used to solve these problems grew out of the successful experiences of Erlang and Palm, among others, in solving telephone trunk problems. The earliest attempts to justify the Poisson distribution as the input distribution of calls to a telephone trunk also laid the basis for using the exponential distribution as the failure law of complex equipment [3].

Since then, the field of preventive maintenance for plant and buildings and the analytically related field of medical screenings have received considerable attention and interest because of the increasing complexity of machinery, building designs and screening programs, and the necessity for such systems to perform their function optimally in terms of profit (or its negation loss), cost, downtime (or its complement availability), and reliability (which can be used to measure the degree of risk or safety). Stochastic modeling and statistical analysis have underpinned much of the MS methodology used for attempting to model and predict the consequences to and behavior of a system (otherwise called a *piece of equipment*—these terms are used interchangeably in this article) when maintenance strategies are applied. Informative accounts

and brief reviews of mathematical techniques applied to maintenance are given in the article titled ***Reviews of Maintenance Literature and Models*** which can be regarded as an accompaniment of the current article.

The purpose of this article is to introduce to engineers, healthcare workers, and others, who have the responsibility for decision making in the general area of equipment maintenance, the potential benefits that can accrue to an organization by an examination of maintenance problems from an MS viewpoint. MS is concerned, to a large degree, with the construction of mathematical models of problem situations whereby alternative actions can be assessed, and the best identified.

This article proceeds by examining “single-unit” systems such as ball bearings, light bulbs, and radio tubes or “complex” systems (regarded as a single entity) such as engines, gearboxes, and TV sets, where it makes sense to assume that only one type of failure can be experienced. Models for profit, cost, downtime, and reliability consequences, given maintenance options, are then formulated along with the necessary statistical analysis and estimation techniques when the lifetime distribution is completely or partially known or completely unknown. The term “lifetime” is defined as follows: Consider a human being, a piece of equipment, an operating system, or a component of such a system. Suppose that the system under consideration is subject to random failure such that the time to failure is random or that the system deteriorates and is no longer capable of functioning properly after a random amount of time. In either case, we refer to such a length of time as the lifetime of the system.

INDUSTRIAL MAINTENANCE PROBLEMS

Industry has clearly recognized the importance of modeling and decision making in maintenance. Maintenance is now not viewed by many as a marginal activity because the

effects of poor maintenance of a plant will become manifest in the medium to long term; however, those who seek to profit in the short term do not concern themselves with effective maintenance—production is all. Consequently, the direct benefit of effective maintenance is difficult to measure; “the true value of maintenance is given in terms of events that do not occur (like a machine not breaking down), which makes the assessment of the value of these measures at best speculative.” Thus, the gains attributable to maintenance are seldom measured either directly through properly designed experiments or by monitoring the consequences for comparison with previous operating data. However, the consequences of changes in maintenance practice are measurable, or at least estimable, through the development of validated modeling. Modelers should work closely with maintenance engineers, particularly on problem recognition and data collection.

Reliable maintenance-related data, which are necessary input for model application, are also difficult to obtain, and records are often incomplete. The modeling of condition-based maintenance is a case in point here. In order for monitored variables relating to condition to be useful in anticipating failures, it is necessary to observe such variables up to and on failure. However, failures are rare, as regular monitoring invariably leads to preventive maintenance being carried out before failure. Thus, while the qualitative effect of such condition monitoring can be seen (fewer failures), the efficiency of such monitoring is difficult to assess (many systems may be overmaintained with components replaced prematurely by conservative maintenance engineers). Again, if the consequences of condition monitoring are to be measured, then a valid model of the monitoring process must be developed. When objective maintenance records are incomplete, the subjective estimation techniques may be considered for modeling maintenance in general [4,5].

IMPORTANCE OF MAINTENANCE

The importance of the maintenance function and maintenance management has grown

over the years. In industry, the reasons for this are as follows:

1. It has been pointed out by Christer [6] that management problems of competitiveness and profitability are more critical because of the high cost of plant, the loss of skilled cheap labor, and competitive pressures on profit margins. Competing in a world market for manufactured goods requires highly automated equipment perceived as leading to the most sustained profit. Expensive high volume production units are required to be available for profitable production, that is, downtime should be minimal. As the existing number of such production units increases, the importance of the task of plant management is evident and will become increasingly so if profit margins are squeezed by competition. Downtime must be avoided, but not at any cost.
2. It has also been pointed out by Christer [6] that customer and marketing demands for products of high quality and high reliability often means reducing human involvement in manufacturing, that is, using automated equipment and robotics. Quality and reliability constraints upon the product then impose in turn corresponding quality and reliability constraints upon the plant producing the product. Management systems such as Just-in-Time and other production control and inventory reduction techniques imply tighter delivery constraints, which again require plant to be reliable, that is, available when needed.
3. As technological advances produce more and more complex systems that are extremely expensive to build and the consequences of their unreliable behavior have become severe in terms of cost, effort, lives, and so on, the interest in maintaining system function has become very important.
4. Widespread mechanization and automation has reduced the number

of production personnel and has increased the capital employed in production equipment and civil structures. As a result, the fraction of employees working in the maintenance area has grown, and so has the fraction of maintenance spending on the total operational costs.

MAINTENANCE AREA

The main industries considered include the oil and chemical industry, railways, transport companies, airlines, steelworks, production lines (e.g., canning lines), and discrete part manufacturers. Also considered are the public sector, for example, electricity generation, defense and infrastructure (e.g., roads), and the health sector, for example, chronic diseases and tumors.

It will assist us conceptually if for the present we restrict attention to the operation and maintenance of plant such as industrial manufacturing equipment, vehicle fleets, power generation facilities, and transport systems.

MAINTENANCE PERSONNEL

While organizations may know their annual expenditure on maintenance, they will not know whether this sum is too high, too low, or about right when viewed against consequence variables in the absence of modeling. For example, we can address the modeling problem in a particular context using monotone processes such as arithmetic, geometric, and arithmetico-geometric processes [7,8].

Maintenance personnel needs to address an inherently stochastic deterioration and failure process. Also, it is very difficult to justify the maintenance budget with its generally unknown contribution to company profits. Therefore, maintenance is often seen as a cost function only, with all the associated negative implications.

Thinking on maintenance should start in the design phase of systems. The type of equipment, the level of redundancy, and the accessibility will strongly affect the maintainability. When purchasing

systems, managers should take future maintenance costs into account. To cover the costs over all phases of systems, the life-cycle-costing concept was introduced. The maintenance concept [9] describes what events (e.g., fault and failure) trigger what type of maintenance (e.g., inspection, repair, replacement); this can be determined both after the design phase and in the operations phase. Once a system is in operation, maintenance has to be planned. By planning, we mean the determination of the execution moments of maintenance activities in accordance with other (e.g., production) plans (e.g., planning shutdowns of major units), the work preparation, and determination of the required maintenance capacity.

MAINTENANCE CONCEPT

Essentially, the maintenance concept [9] is the set of rules prescribing what maintenance is required and how demand for it is activated for a system. The introduction of large, complex systems in production, the growing awareness of the natural environment, and increasing labor costs imply the introduction of more sophisticated maintenance concepts such as reliability-centered maintenance reaching to qualitative maintenance concepts.

Maintenance is the totality of activities intended to retain a system in, or restore it to, a state in which it can perform its required function. In this definition, "retaining in" and "restoring to" correspond to preventive maintenance or condition monitoring and corrective maintenance (which is carried out upon failure and thus called *breakdown maintenance* as well). Failure denotes the transition of a system to the state in which it is incapable of fulfilling its function. The number of failures during actual operation should be decreased to as few as possible by means of preventive maintenance. In particular, as the system ages, it needs more frequent maintenance activities to the extent that costs and circumstance permit.

We are concerned with a system liable to (costly) failure. Failure is taken here to

mean a breakdown or catastrophic event, after which the system is unusable until repaired or replaced. It may also be simply deterioration to a state such that the repair can no longer be postponed. Operational definitions of failure and defectiveness used in the plant concerned are usually adopted for modeling purposes. The judgment that a system is defective is made by maintenance technicians or engineers.

Preventive maintenance (PM) is some activity carried out at (equal or unequal) intervals with the intention of reducing or eliminating the number of failures occurring or of reducing the consequences of failure in terms of, say, downtime or operating cost. This sort of activity aims at retaining part of a technical system in the operable state; this compares with alternative corrective maintenance which is carried out upon failure and aims to restore the failed part of the system to the operable state.

PM has been described as the most difficult activity to model in the field of maintenance [10]. The complexity of modeling PM stems from the difficulty of quantifying the effects of performing PM at different intervals. The traditional method for modeling PM is to model the relationship between the PM interval and the operating cost per unit time or the system availability.

Also, a great deal of the literature has been devoted to condition-monitoring models. In these models, it is assumed that there exists an indicator whose value is related to the condition of the unit. One of the successful models in this field is delay-time analysis [11]. Condition monitoring focuses on techniques that predict failures using information on the actual state (e.g., lubricant debris analysis, vibration monitoring) of equipment.

Reliability-centered maintenance (RCM) directs maintenance efforts at those parts and units where reliability is critical [12,13]. It can be regarded as the more qualitative approach to maintenance where optimization models are the quantitative approach. RCM is probably the global analysis method which is most frequently used for identifying a cost-effective maintenance program for a plant [14]. The goal of RCM is to identify the optimal maintenance for each component, taking

safety requirements, maintenance costs, and failure costs into account. No doubt the RCM methodology gives a practical and structured approach for each component. However, there is no sound foundation for claiming that the maintenance strategy derived from the RCM approach is in any sense optimal [15].

Total productive maintenance (TPM), another qualitative approach, centers on solving maintenance problems using quality circles. Nakajima [16–18] has defined TPM as an innovative approach to maintenance that optimizes equipment effectiveness, eliminates breakdowns, and promotes autonomous maintenance by operators through day-to-day activities involving the total workforce. Thus, TPM is not a specific maintenance policy; it is rather a culture, a philosophy, and a new attitude toward maintenance. The salient features of TPM are the involvement of operators in carrying out autonomous maintenance by participating in cleaning, lubrication, house-keeping, minor repair, adjustments, and so on. The benefits of TPM can be very tangible. Through implementation of TPM, organizations have separately been able to increase the production volume, and reduce downtime and rate of defective products. TPM also offers various intangible benefits such as fostering team work, increasing morale and safety, and nurturing the workforce.

MANAGEMENT SCIENCE (MS) MODELING

Yet, it is very difficult to answer the main questions faced by maintenance personnel: whether its output is produced effectively in terms of its contribution to company profits and efficiently in terms of manpower and materials employed.

In theory, maintenance personnel facing these problems could have benefited from the advent of an area of MS called *maintenance optimization*. Basically, a maintenance optimization model is a mathematical model in which both costs and benefits of maintenance are quantified and in which an optimal balance between both is obtained.

Here, we define maintenance optimization models as mathematical models whose aim is

to find the optimal balance between the costs and benefits of maintenance, while taking all kinds of constraints into account. In almost all cases, maintenance benefits consist of savings on costs which would be incurred otherwise (e.g., less failure costs).

In general, applications of maintenance optimization models cover the following four aspects:

1. a description of a technical system, its function, and its importance;
2. a modeling of the deterioration of the system in time and possible consequences for the system;
3. a description of the available information about the system and the actions open to management; and
4. an objective function and an optimization technique which helps in finding the best balance.

The maintenance objectives can be summarized under the three headings as follows:

1. ensuring system function,
2. ensuring system life (e.g., civil structures like buildings, roads, dam), and
3. ensuring safety (e.g., airplanes, nuclear plants, and chemical plants).

For production equipment, sustaining system availability in a cost-effective manner should be the prime maintenance objective. Here, maintenance has to provide the right (but not maximum) reliability, availability, efficiency, and capability (i.e., producing at the right quality) of production systems, in accordance with the need for these characteristics. In principle, it is possible to give an economic value to the maintenance results and a cost-balance can be done.

Maintenance optimization models have numerous benefits and advantages. Examples are as follows:

1. different maintenance policies can be evaluated and compared with respect to cost-effectiveness and reliability characteristics;

2. insight can be obtained on the structure of optimal policies, like the existence of an optimal control-limit policy;
3. models can assist in defining the maintenance concept—how often to inspect or to maintain; and
4. models can be of help in determining effective and efficient overall scheduling plans, taking all constraints into account.

MAINTENANCE MODELING

Decisions associated with managing the maintenance function could be divided into engineering decisions and operational decisions. The former relate to the choice of what engineering actions to actually take and when to take them (i.e., determine the maintenance concept itself), while the latter relate to the operations aspect of implementing decided engineering actions (e.g., scheduling shutdown, managing manpower, logistics, and inventory control); hence influencing the efficiency of implementing a maintenance concept.

By maintenance model, we mean a model specifically built for the maintenance function and which, unlike the other models used in the management of maintenance, actually addresses decision makers relating to the engineering issues and consequences as opposed to operational choices [19].

A maintenance model is a device that enables one to relate a decision variable to its consequence in a maintenance concept. Data modeling is well understood, especially Weibull modeling [20], and reliability-based modeling is still a very novel concept among engineers; especially the modeling of engineering aspects of maintenance. Failure data will be modeled, but not maintenance decision problems (e.g., Weibull analysis is applied to a set of reliability data collected under a particular maintenance practice).

The problem here is the difficulty of relating maintenance expenditure to production output, quality, and cost. Overcoming this requires maintenance modeling, which

relates, for example, the following maintenance decision variables to outputs or returns of interest.

1. Cost-effective maintenance for production is possible if the consequences upon production of maintenance activity are both recognized and known quantitatively. Understanding such a complex interaction requires a maintenance modeling exercise. The notion of actually modeling maintenance is novel. Routinely collected data are usually inadequate for the maintenance modeling task, and that additional information will usually need to be obtained from experienced maintenance engineers in order to construct maintenance models.
2. The degree of interest one has in the reliability of a system and the standard of reliability to be achieved are closely coupled to the consequences of unreliable behavior. Improving reliability will, in general, cost more, but the achievement of reliability usually saves money and sometimes saves lives. Accordingly, the need to maintain an "economic balance" determines the level of reliability, to which one should aspire in the design/maintenance of components and systems. Instead of asking of a system, "Is it reliable?" one should ask, "Is it reliable enough?" Finding an answer to this question obviously requires the quantification of reliability, which is achieved by using the theory of probability and statistics.

The relationship between reliability, cost, and maintenance requirements is important. Examples of high-reliability systems are all around us, from aircraft systems, electric power generating stations and chemical plants to communication systems, and computer systems.

Improving the reliability of a system costs money and is economically justified if the decrease in the expected cost of failure is at least equal to the expected cost of the improvement in reliability. In the past, only high-technology areas in

aerospace and defense were the recipients of reliability improvement efforts. However, as we enter the twenty-first century, high technology is permeating almost all aspects of life. The need to maintain high levels of productivity and competitiveness in the international marketplace indicates that efforts at improving reliability can have a broad, positive impact in manufacturing and service industries as well. Once an improvement in reliability is shown to be justified economically if the data inputs are realistic, the question of whether it is too expensive becomes a moot point. In all our discussions, we should not overlook the ever-increasing cost of liability.

The options available for improving reliability obviously depend on the problem at hand. In most cases, the options can be grouped into four basic categories:

1. providing redundancy,
2. designing environmental capability,
3. performing environmental testing (detailed studies by manufacturers about the failures of their products resulted in better designs, with less failures as a result), and
4. selecting maintenance strategy and servicing.

In practice, a combination of the four options would be considered, and some acted upon if felt appropriate. The nature of the mix will depend on the ratio of incremental benefit to incremental cost as a function of cost for each of the four options, the role played by risk, and budgetary considerations. Within specific cases, the definitions of "incremental benefit" and "incremental cost" are often nontrivial.

There are two aspects to modeling maintenance, the first being to seek to reduce the number of faults arising and their consequence, and the second the subsequent maintenance concept as an aid to decision making. To reduce the number of defects arising, it is necessary to identify the cause of defects and possible means of removing or reducing the cause. This is a key part in forming a maintenance concept [9] and

is directly associated with snapshot modeling [21]. When there are no data to be fitted, subjective information from engineers is of value and can be obtained by administering questionnaires [22]. At any maintenance intervention, there is a wealth of information potentially available, both objective (e.g., what has failed, what is being replaced) and subjective (e.g., what caused the defect and whether the occurrence is preventable). A systematic method of doing this has been called *snapshot modeling*.

Maintenance optimization models, embedded in decision-support systems, provide an objective and quantitative way of decision making in which the expected consequences of not maintaining, or maintaining in a different way, become clear. Although the number of real applications of maintenance models published in the literature is relatively small, these case studies show that mathematical models are a good means of achieving both effective and efficient maintenance. The factors that may have hampered the applications are discussed in Dekker [23], Scarf [24], and Dekker and Scarf [25].

MEDICAL MAINTENANCE

Someone who has worked on both industrial and medical maintenance problems will be struck by the differing preoccupations of workers in the two fields. Healthcare workers are very interested in ensuring that their models fit the real world, and in fact their distrust of models is such that, even after formulating the models, they will still wish to test the efficacy of screening in a particular age range directly by a medical trial. However, although they will evaluate different policies, they do not have the concept of an optimal policy. In industrial maintenance modeling, in contrast, there is great interest in finding optimal policies for many seemingly arbitrary models, but often little interest indeed in comparing models with data. It is seldom indeed that there is any attempt to show by direct statistical methods that a move to optimize maintenance has produced a net benefit.

Periodic or nonperiodic medical screening (or mass medical screening)—the deliberate examination of a single individual (or a large group of individuals) in a search for disease at its earliest stages—is a logical extension of the role of preventive medicine. In the medical screening problem, we seek the vector of ages at which people should be screened in order to minimize a suitable cost function. There is a close analogy with industrial inspection, where a machine is inspected for defects (that can give rise to failures) several times during its service life. In the industrial case, defective components can be replaced or repaired, hence averting a costly failure. One medical analog of such a defect is a tumor, which once detected at screening can be treated, [26] and the journal *Health Care Management Science*. The rationale of screening is that the prognosis is better when treating malicious tumors. In industrial inspection, a machine would probably be inspected for all possible defects simultaneously. In medical screening, however, inspection merely attempts to detect one particular type of defect. This means that mortality from other causes also occurs, and must be modeled.

If it is established that a particular screening procedure is medically desirable, there remains the practical necessity of determining whether or not the costs involved make the procedure worthwhile. Clearly, in these days of scarce resources, it is necessary to search for screening policies that will make the procedures as efficient as possible. The aim is to choose a screening policy that minimizes, say, the total cost of screening. Many variables, some of them stochastic in nature, influence the efficiency of a screening program. One difficulty here is that, in general, it is not possible to express the risks, costs, and benefits of a screening procedure in the same common and easily understood measure, for example, monetary units. The testing expense includes easily quantifiable economic costs such as those of the labor and materials needed to administer the testing. However, there can also be other important cost components which are more difficult to quantify; for example, in the case of a human population subject to medical

screening, the cost of side effect and that of false positives or false negatives, which entail both emotional distress and the need to do unnecessary follow-up testing and even the risk of physical harm to the testee, for example, the cumulative effect of X-ray exposure. We agree that the usual cost-benefit analysis is unlikely to suffice in this very complex situation involving pain, suffering, and human life. Nevertheless, some quantitative guides are essential for making good decisions about screening procedures. Suitable mathematical models, if available, would help the medical decision makers confronted with this complex situation.

Many of the techniques and approaches of industrial maintenance management mentioned in the sections titled "Industrial Maintenance Problems," "Importance of Maintenance," "Maintenance Area," "Maintenance Personnel," "Maintenance Concept," "Management Science (MS) Modeling," and "Maintenance Modeling" are relevant to medical screening problems.

CONCLUSIONS

Research into production technologies should consider maintenance. The significance and complexity of maintenance in modern production and manufacturing systems indicate that maintenance should be viewed as an increasingly important area of study and research.

In the follow-up article "Reviews of Maintenance Literature and Models", we review some basic maintenance models such as age replacement and block replacement. In addition, we list a series of survey papers, handbooks, and monographs on maintenance research dating from 1960 to 2010.

MANAGEMENT OF NATURAL GAS STORAGE ASSETS

DEREK WANG
Desautels Faculty of
Management, McGill
University

In North America and Europe, natural gas storage plays an essential role in managing the mismatch between energy supply and demand. Consider the United States as an example [1]: daily production of natural gas is relatively constant at 52 billion cubic feet per day (Bcf/d), whereas consumption exhibits significant seasonal variations: 55 Bcf/d during the nonheating season (April through October) and 70 Bcf/d during the heating season (November through March). The seasonal supply–demand imbalance makes it necessary to build underground natural gas storage facilities throughout the United States, in particular, in the Gulf production area and the North East and Midwest consumption areas.

There are three main types of underground natural gas storage facilities [2], (i) depleted oil/gas reservoirs, (ii) aquifers, and (iii) salt caverns. There are 410 underground storage sites in the United States, with a total storage capacity of about 8.8 trillion cubic feet (Tcf) in 2011 [3]. The Federal Energy Regulatory Commission (FERC) Order 636 in 1992 requires that storage facilities operate on an open-access basis such that storage owners can only control enough capacity to maintain system integrity and the rest capacity must be made available for lease to third parties. In such a deregulated market, the owners of storage facilities include pipeline companies, local distribution companies, and independent storage service providers. Deregulation opens the storage market to competition and expands the use of storage beyond its traditional role of supply–demand balancing. Today, storage operators can move gas into and out of storage to capitalize on gas price variations.

Physical constraints need to be considered in managing natural gas storage assets. The injection and withdrawal capacities of natural gas are governed by the Bernoulli's law and, hence, depend on the pressure differential between the storage and the pump/pipeline. The more the natural gas is in the storage, the higher the pressure in the reservoir, hence the slower the maximum injection rate and the faster the maximum withdrawal rate. For the ease of implementation in reality, industry practitioners approximate the real injection/withdrawal capacities with piece-wise constant capacities, which are called *ratchets* as they ratchet up and down with inventory. For a typical natural gas depleted reservoir storage facility [4, p. 456], the maximum injection rate is initially constant and then declines steadily in response to the higher pressure within the gas storage as working inventory builds up. A similar but reverse trend is observed for the withdrawal rate. It takes about four months to fill up or deplete the storage and eight or nine months to complete a cycle. Salt caverns are relatively small but provide the highest withdrawal and injection rates relative to their storage volume. Aquifers lie somewhere in between. The depleted gas/oil reservoirs hold more than 80% of the total capacity in the United States and are mainly used to meet seasonal demand variations and capture seasonal price differentials. Owing to their high deliverability, the salt caverns are widely used as peak-load storage to meet demand variations and exploit profit opportunities in the time scale of weeks, days, and even hours.

Storing and releasing natural gas also involve operational frictions. For example, the pumps of the storage facility use some of the gas as fuel [5]. If q units are to be added to the storage, the firm needs to purchase $(1 + \alpha)q$ units; if q units are withdrawn from the storage, a fraction βq will be lost and $(1 - \beta)q$ can be sold. In addition to the volume losses, the firm also incurs a variable

cost of $c_\alpha q$ when q units are stored and a cost of $c_\beta q$ when q units are withdrawn. These costs can cover the use of pumps and other equipment. For depleted reservoirs, the injection loss rate α is typically between 0% and 3%, the withdrawal loss rate β is between 0% and 2%, and the variable operating costs c_α and c_β are below \$0.02 per million British thermal unit (mmBtu).

Storage assets owners and third-party lease contract holders have great incentives to optimize the utilization of storage facilities to maximize their profit. The value of storage assets primarily arises from the natural gas summer-to-winter price differentials. Reflecting the seasonal supply-demand imbalance, the natural gas futures market on the New York Mercantile Exchange (NYMEX) prices summer contracts at a significant discount in relative to the winter contracts. Figure 1 shows the natural gas futures prices observed on the first trading day of March in recent years. The seasonal price pattern allows a storage operator to capture the summer-to-winter price spread by injecting gas in the summer and withdrawing in the winter. In March, the

firm (owner or leaseholder of a natural gas storage asset) can decide an injection-and-withdrawal schedule from April through to the next March by taking long or short positions on futures contracts. Once these futures positions are determined (e.g., by solving a static profit maximization problem subject to certain physical constraints discussed in detail in the next section), the firm essentially locks in a risk-free profit. This value is referred to as the *intrinsic value of the storage asset*.

Optimization of storage operations is considerably more challenging than solving for intrinsic value, because it involves multiple interacting real options, that is, options to store or withdraw within capacity limits in every period. References 6 and 7 provide the theoretical background of real options. A crucial distinction of applying real option approach to storage valuation from its general application is the physical constraints constraining the procuring/selling decisions. Explicit analysis of storage operations is possible when physical constraints are ignored [8]. Analytical valuation of the general storage options typically does not exist because

Figure 1. Natural Gas Forward Curve on the First Trading Day of March (2009–2012).

of the injection and withdrawal constraints. The section titled “Exact Model of Storage Operations” outlines the management of gas storage under the real option framework. In general, finding the optimal storage policy is analytically and computationally challenging. Consequently, heuristic methods have been developed in practice and studied in academia and are discussed in the section titled “Heuristic Policies.” Theoretical and numerical techniques have been proposed to improve heuristics and are summarized in the section titled “Beyond Heuristics.” A brief discussion of potential future works is presented in the section titled “Future Directions.”

EXACT MODEL OF THE STORAGE OPERATIONS

The valuation under the real option framework can be formulated as a continuous-time stochastic control problem [9–12] or discrete-time stochastic dynamic program [4,10,13,14].

We first explain the discrete-time models. At the beginning of period t , the futures price for delivery in period t is maturing, denoted as f_{tt} . The firm sees the maturity price and other futures prices f_{ts} ($s > t$) and decides the quantity to purchase or sell at price f_{tt} . The settled amount is then stored into or withdrawn from the storage over the entire period. Under the standard no-arbitrage assumption, the futures prices are martingales under an equivalent martingale measure Q . The firm can adjust futures positions any time before they expire. As futures prices are martingales, those adjustments do not affect the expected value of the energy storage because the expected marked-to-market cash flow is zero under Q -measure. Owing to the operational frictions, consider $\tilde{f}_{ts} = e^{-R(s-t)}[(1-\beta)f_{ts} - c_\beta]$ as the forward selling price and $\tilde{f}_{ts}^b = e^{-R(s-t)}[(1+\alpha)f_{ts} + c_\alpha]$ as the forward buying price of inventory discounted to the first period. It is straightforward to verify that both $\tilde{f}_{ts}$ and $\tilde{f}_{ts}^b$ are martingales. Let $\tilde{f}_t = (\tilde{f}_{ts} : s \geq t)$ denote the discounted forward prices observed at the beginning of period t . Let y_t be the ending

inventory in period t , which is decided by the firm at the beginning of period t . The storage valuation problem can be written as:

$$V_t(x_t, \tilde{f}_t) = \max_{y_t \in [\underline{y}(x_t), \bar{y}(x_t)]} r(y_t - x_t, \tilde{f}_{tt}) + E_t^Q[V_{t+1}(y_t, \tilde{f}_{t+1})],$$

where $r(q, \tilde{f}_{tt})$ is the one period revenue function; E_t^Q denotes the expectation under the equivalent martingale measure Q conditional on information until period t ; and y_t is bounded between the inventory-dependent capacities $\underline{y}(x_t) = x_t + \underline{\lambda}(x_t)$ and $\bar{y}(x_t) = x_t + \lambda(x_t)$. Here, $\lambda(x_t) \geq 0$ models injection capacity and $\underline{\lambda}(x_t) \leq 0$ models withdrawal capacity. In the last period, the firm sells as much as possible to maximize profit, $V_N(x_N, \tilde{f}_{NN}) = -\tilde{f}_{NN} \lambda(x_N) - \underline{y}(x_N)p$, where $p \geq 0$ denotes the penalty per unit of inventory at the end of period N , and p is realized in period N and may depend on the market price [9,12,15].

Continuous-time representations of gas storage valuation as a Markov decision process are described in Refs 9–12. Let $\pi(t, x_t, p_t, q_t)$ denote the instantaneous profit at t , where the inventory level is x_t , p_t is the gas price under Q -measure and follows Markov continuous-time stochastic process, and the injection/withdrawal rate q_t is bounded between injection/withdrawal capacities. Then, the expected profit-to-go at t under some admissible policy u is

$$V_t^u(x_t, p_t) = \int_t^T e^{-R(s-t)} \pi(s, x_s^u, p_s, q_s^u) ds + e^{-R(T-t)} V_T^u(x_T^u, p_T),$$

where the inventory evolves according to $dx_t^u = -q_t^u dt$, and $V_T^u(x_T^u, p_T)$ is the terminal value of inventory. The objective is to find an admissible policy to maximize the profit

$$V_t(x_t, p_t) = \sup_u V_t^u(x_t, p_t).$$

We comment that continuous-time and discrete-time formulations can be used for both spot and futures market valuations. In

the discrete-time model, the formulation continues to hold for spot market valuation, with f_{tt} interpreted as the spot price in period t and f_{ts} interpreted as the forecast in period t for the price in period s . The continuous-time model can be interpreted as valuation through either spot or futures market, as p_t can represent the spot price or the price of the near-month forward contract. Therefore, Carmona and Ludkovski [12] state, “given a variety of quoted gas prices (spot, balance-of-the-month, futures, etc.), we remain agnostic about the precise interpretation.”

Price Models

Price dynamics are crucial in the valuation problem, and a broad range of price models have been used. Driftless geometric Brownian motions are widely used to model the futures prices under the equivalent martingale measure [4,14,16,17]. In an n -factor model, f_{ts} , the price of contract with maturity s , evolves according to

$$\frac{df_{ts}}{f_{ts}} = \sum_{i=1}^n \sigma_i(t,s) dW_t^i,$$

where W_t^i is an independent standard Brownian motion and the corresponding volatility $\sigma_i(t,s)$ is a function of time and maturity. The spot price is usually modeled as a mean-reverting process. Jumps are often incorporated into the mean-reverting dynamics to model price spikes observed in the natural gas markets [9–11]. Therefore, the general form of spot price is

$$dp_t = \mu(t,p_t)dt + \sum_{i=1}^n \sigma_i(t,p_t)dW_t^i + \sum_{j=1}^k \delta_j(t,p_t)dN_t^j,$$

where N_t^j is an independent Poisson process and δ_j is the jump size. Some articles do not explicitly specify the processes followed by futures prices but derive futures prices from the spot price process [17,18].

Two salient features of natural gas price are convenience yield and seasonality. Convenience yield, defined as the premium of holding the physical commodity over the futures contract, can be incorporated into the spot price drift term $\mu(t,p_t)$ as in Ref. 18. Seasonality in futures market is reflected by the shape of the forward curve and the time-dependent volatility $\sigma_i(t,s)$. Seasonality in spot price can be captured by $\sigma_i(t,s)$ and seasonally adjusted mean-reverting level in the drift term $\mu(t,p_t)$ [13,16,17].

Carmona and Ludkovski [12] abstract from specific price models by treating the price as a general multidimensional Markov process. They demonstrate that their simulation approach is able to deal with complex price processes such as mean-reverting process with jumps. In general, high dimensional models more precisely capture price dynamics but are more difficult to estimate and require more computational efforts. Further discussions of gas price modeling can be found in Ref. 19.

Structure of Optimal Policy

Structural properties of the optimal policy have been documented. Hodges [8] formulates the storage operation as an infinite horizon optimal control problem without operational frictions. The optimal control is to fill up the storage as soon as the price falls below a critical price p^* and sell stock as soon as price rises above p^* . References 14 and 20 show that the optimal policy is characterized by two stage- and price-dependent base-stock targets: if inventory falls between the two targets, it is optimal to do nothing; otherwise, the firm should inject or withdraw to bring the inventory as close to the nearest target as possible. In the continuous-time framework [12], the optimal policy has a bang-bang structure. The control policy has only three choices: inject at the maximum rate, withdraw at the maximum rate, or do nothing. A sufficient condition for the above structural result is that the storing (releasing) capacity function (e.g., ratchets) is concave (convex) in inventory. The dependence of operation policy on price process has also been investigated [10]. If the price is stochastically increasing, a mild assumption

holding for many price processes, then, under higher price, the operator should inject less or withdraw more.

Numerical Methods

Practitioners and researchers have resorted to numerical methods for solving the exact storage operations problem. Three computational methods are used: numerical partial differential equation techniques [9,11,12], binomial/trinomial trees [21,22], and Monte Carlo simulation [12,13]. Least squares Monte Carlo method (approximation of the expected value function with ordinary least square regression) to value storage assets can incorporate very general physical constraint [13]. The regression may become slow when the full spectrum of spot and forward prices is considered. In the optimal switching approach [12], the model can accommodate general price models and allows the decision maker to make frequent trading decisions. Tree-based methods can use one- or two-factor price models, and three-factor model has never been implemented so far.

HEURISTIC POLICIES

Significant computational burden arises in real applications of the exact stochastic dynamic program where the optimization problem involves multidimensional futures prices evolving in a larger state space over a longer horizon. As stated in Ref. 14, “the number of maturities N associated with natural gas storage contracts is at least twelve, so that model is computationally intractable because of its high-dimensional state space.” Consequently, heuristic methods have been developed in practice and studied in academia.

Practitioners typically use two heuristic strategies to value seasonal energy storage: the rolling intrinsic (RI) approach and the rolling basket of spread options approach [23–26]. They are also referred as *reoptimized intrinsic value strategy* and *reoptimized linear program strategy*, respectively, in Ref. 14. Both policies are well received by the industry practitioners in the operation of low deliverability storage because of

their simple logic and ease of implementation. However, the efficacy and accuracy of these heuristics have not been established for high deliverability storage for which operations are scheduled more frequently on daily or hourly basis. The results in this section are all derived for the operation of low deliverability storage.

Rolling Intrinsic Policy

To define the RI policy, we first define the intrinsic policy, a policy that decides in the first period the actions to be performed in each of the remaining periods. The intrinsic policy is found by solving an optimization problem using only the forward prices seen in the first period. The corresponding value is called the *intrinsic value*. The RI policy is pseudodynamic: Every day, the firm solves a static intrinsic value optimization problem to decide the futures positions and reoptimizes the futures positions in each period by solving the intrinsic valuation problem using the updated forward prices. The corresponding value is referred to as the *RI value*.

The RI policy can be mathematically formulated as a dynamic programming problem [4]. First, given the discounted forward prices $\tilde{f}_t$, the intrinsic value of the storage is determined by:

$$\begin{aligned} V_N^I(x_N, \tilde{f}_t) &= -\tilde{f}_{tN} \underline{\lambda}(x_N) - \underline{y}(x_N) E_t^Q[p], \\ V_s^I(x_s, \tilde{f}_t) &= \max_{y_t \in [y(x_t), \bar{y}(x_t)]} r(y_s - x_s, \tilde{f}_{ts}) \\ &\quad + V_{s+1}^I(y_s, \tilde{f}_t), \quad t \leq s < N. \end{aligned}$$

Let $y_t^\dagger$ be the futures position on the maturing contract $\tilde{f}_{tt}$ in period t , obtained from the above deterministic intrinsic value optimization. Computing $y_t^\dagger$ requires no assumptions on the stochastic evolution of the forward curve. In RI policy, the firm solves the above deterministic optimization problem in every period with updated forward curve $\tilde{f}_t$ and adjusts the futures positions accordingly. The RI value of the storage is then determined by:

$$V_N^{\text{RI}}(x_N, \tilde{f}_N) = V_N^I(x_N, \tilde{f}_N),$$

$$V_s^{\text{RI}}(x_t, \tilde{f}_t) = r(y_t^\dagger - x_t, \tilde{f}_{tt}) + E_t^Q V_{s+1}^{\text{RI}}(y_t^\dagger, \tilde{f}_{t+1}),$$

$$1 \leq t < N.$$

The RI policy solves a deterministic optimization problem every period and may miss potential option values rising from the stochastic evolution of the forward curve. Further discussion of missing option value is presented in the section titled “When Are the Heuristics Suboptimal” in this article.

Rolling Basket of Spread Options Approach

The spread options approach benchmarks the natural gas storage value using a portfolio of calendar spread options [14,26]. According to the NYMEX rule, “buying a call (put) on the natural gas calendar spread options contract will represent a long (short) position in the closer natural gas futures contract month and a short (long) position in the longer-dated natural gas futures contract month.” In practice, injection and withdraw operations always appear in pairs: If one unit of natural gas is injected into the storage, it will be withdrawn later at some date. The operation of injecting one unit of natural gas at time t at price f_{tt} , and then withdrawing it later at time s ($s > t$) at price f_{ts} resembles the exercise of a European call spread option. The real profit of such an operation is random because of the stochastic futures prices, but the expected present value of such an operation can be approximated by the price of the spread option P_{ts} . P_{ts} can be numerically computed or approximated using Kirk’s formula.

Suppose now is day 1, and as the owner of the storage assets, we have decided a certain injection/withdrawal schedule. Then, the schedule can be thought of as a basket of spread options. To maximize the expected profit under this schedule, we only need to find the optimal portfolio with the highest value. Let q_{ts} ($s > t$) be the quantity of the spread option P_{ts} in the portfolio. Then, the optimal portfolio can be found as follows:

$$\max_{q_{ts}} \sum_{t < s} P_{ts} q_{ts}$$

$$\text{s.t. } q_{ts} \geq 0,$$

where q_{ts} subject to physical constraints.

The physical constraints ensure that the injection/withdrawal operations represented by the portfolio are compatible with the physical limits of the storage. The number of variables depends on planning horizon. For the standard April-start/March-end contract, there are 66 potential spread options to trade. The above optimization yields the day 1 intrinsic value of the storage. The portfolio is dynamically adjusted every period by resolving the above optimization problem conditional on updated forward curve information, that is, the portfolio of spread options is getting rolled. The above portfolio optimization problem reduces to linear optimization under constant injection/withdrawal capacities. Integer linear programming is needed to deal with nonlinear capacities.

Performance of Heuristics

The RI policy has near-optimal performance in many circumstances [14] but can significantly underperform in some cases [4]. Lai *et al.* [14] used an approximate dynamic programming approach coupled with information relaxation to derive upper bounds on value of storage with constant capacities. They assess the performance of different approaches under either 12-month or 24-month contract terms starting from four different dates in 2006. Using a two-factor price model, Wu *et al.* [4] examined RI valuation in each of the nine years from 2001 to 2009 under different ratchets and discount rates. The RI valuation has a median value loss of 0.59% compared with the optimal valuation. For 15% of the instances, the value loss of RI policy is at least 1% (1% value loss is roughly \$0.1 million for a 10-trillion Btu storage under \$1 per million Btu seasonal price spread). The maximum value loss is 9.23%.

In practice, people often find that spread options approach yields higher value than the intrinsic approach, because the former captures the option value. But, when the two strategies are “rolled” or reoptimized frequently, their performance is empirically the same in terms of the expected value [23,24]. Gray and Khandelwal [24, p. 4] state,

“we have found empirically that, in general, the rolling intrinsic value is equal to the rolling basket value.” This is also confirmed by Ref. 14, which finds that both strategies capture more than 97% of the upper bound on average.

In the RI approach, the funding risk of daily mark-to-market exposure can be significant. A large marked-to-market loss might require a posting of collateral. Although this would ultimately be mitigated by the execution of the physical hedge, funding capital might be at risk, possibly resulting in early termination. In the basket spreads, daily marked-to-market profits and losses are part of the game, as both must be born out in a true dynamic hedging scenario. In terms of value distribution, the RI has a guaranteed lower bound equal to the initial intrinsic value, thereby creating a “truncated” distribution. This is because it only rebalances the futures positions on favorable price movements.

When Are the Heuristics Suboptimal?

In order to improve the operations, it is critically important to understand why the heuristic decisions deviate from the optimal decisions. Several situations can be identified. These situations serve as “red flags” for practitioners to consider their operations before applying the RI strategy.

Some situation has a flavor similar to the value of waiting found in real options applications. For example, during the peak selling season, if all future prices are expected to be lower than the current price, RI policy is to sell as much as possible. But, waiting may be beneficial because the firm has the flexibility of scheduling operations to capture the expected maximum of future prices, which may be higher than the current price. Waiting for a month means that the firm has one less month to schedule the remaining operations, and it would have to sell inventory at whatever market price. Waiting may also forgo the option of counter-seasonal operations (e.g., buying in the selling season). On top of the value derived from seasonal price spread, the option of counter-seasonal operations provides additional value from within-season price fluctuations. Thus, striking a balance between the value of waiting

and the value of potential counter-seasonal operations is necessary.

When the storage can be sold later in the season and the current price is the lowest compared to the expected future prices, waiting for higher prices might seem to be optimal, as prescribed by the RI strategy. Contrary to the intuition, the optimal strategy may involve selling inventory at the lowest price. In fact, if the firm sells one unit at the current low price, it will sell one less unit at the lower of the two future prices (avoiding the adverse price), which may be even lower, in expectation, than the current price.

BEYOND THE HEURISTICS

Heuristic methods in last section are developed based on practitioners’ intuitions and experiences, rather than derived from real options theory, because of the theoretical challenges in analyzing storage options. In recent years, several approaches have been developed by academia to close the gap between the heuristics and optimality. At \$5 per mmBtu, filling a typical 10-Bcf depleted reservoir storage facility costs \$50 million. With a summer-to-winter spread of \$1 per mmBtu, the storage is expected to make a profit of at least \$10 million. Even small improvement in operations can bring significant benefit to the storage owners and lease contract holders.

Upper Bounds of Storage Value

Upper bounds on the storage value can be derived with approximate dynamic programming and benchmark various policies when exactly solving for the optimal storage value is not feasible under high dimensional price models [14]. In this approach, the intractable high dimensional stochastic dynamic program is transformed into a low dimensional dynamic program through information relaxation, where the decision maker is given anticipative information on price evolution and the information renders the program simpler to solve. The approach is quite general and can accommodate different price models and long planning

horizons (24-month contract term is used in Ref. 14). The approximate dynamic programming method consumes more CPU time than RI or rolling spread options approach but can generate very tight and effective upper bounds. The results confirm that RI and rolling spread options methods are nearly optimal for spring, summer, and fall scenarios. The gap between the RI/rolling spread options and the upper bound is wider for those winter scenarios.

Price-Adjusted Rolling Intrinsic

The idea of the price-adjusted rolling intrinsic (PARI) policy is to adjust the forward curve to bring the adjusted intrinsic values closer to the option values and then apply the RI policy on the adjusted forward curve to improve the RI decision [4]. It can be analytically proved that there exists a set of price adjustments under which the adjusted intrinsic values equal the option values in a three-period model under general price distributions and capacity functions. The same logics are then adapted to N -period problems. While computing PARI decision requires assumptions on the stochastic evolution of the forward curve, the price adjustment can be done without solving a stochastic dynamic program, and hence the PARI policy remains computationally tractable.

FUTURE DIRECTIONS

There are several untapped issues on the management of gas storage. First, owing to the illiquidity of the spot market, perfect hedging does not exist. Hence, advanced risk objectives may be taken into account to complement the existing models of expected value maximization. Moreover, the proliferation of gas-fired power plants has spurred the rapid growth of high deliverability storage capacity in recent years. It is of significant value to develop heuristic methods for storage with daily and hourly reoptimization, where existing heuristics may fail because of heavy computational burden and lack of financial instruments on a more granular time scale. Finally, existing models typically make a simplifying assumption that the capacities

are constant to help simplify analysis. "This assumption, widespread in the industry, is very convenient," as commented in Ref. 5, p. 436, and may be a good approximation when the storage level is within a certain range. However, the importance of real level-dependent capacities has been recognized in Ref. 23, p. 1: "Very often, realistic issues such as bid/ask spread, discounting and, level-dependent rates (ratchets) and hard inventory level constraints are ignored or assumed away . . . Critically, storage valuation must be consistent with the physical constraints of the storage field." It is of both practical and academic value to understand how inventory-dependent capacities impact storage operations and storage value.

MANAGEMENT SCIENCE/ OPERATIONS RESEARCH SOCIETY OF MALAYSIA

ILIAS MAMAT
Operations Research Society of
Malaysia, Permodalan Nasional
Berhad, Kuala Lumpur,
Malaysia

ORIGINS OF MSORSM

The Management Science/Operations Research Society of Malaysia (MSORSM) [1] was registered as a professional society under Section 7, Societies Act of Malaysia 1966, on July 19, 1986. The society was inaugurated on October 5, 1986. MSORSM was the 36th national society to become a member of the International Federation of Operational Research Societies (IFORS), the 9th national society to become a member of the Association of Asian Pacific Operational Research Societies (APORS), and is a member of the Confederation of Scientific and Technological Associations of Malaysia (COSTAM).

THE MISSION, STRATEGIES, AND ACTIVITIES OF MSORSM

The mission of MSORSM embodies several goals as follows:

- to be a well recognized body representing, promoting, and advancing management science/operations research;
- to play the lead role for the advancement of a progressive and well informed management science/operations research community;
- to promote and develop management science/operations research as an interdisciplinary field;

- to foster the application, wherever appropriate, in the widest possible exchange of information and ideas on related subjects; and
- to generate a group of actively participative communities for the advancement of the discipline of management science/operations research both within and outside Malaysia.

MSORSM works to achieve these objects through several strategies, including

- positioning into key committees that involve management science/operations research in the industry;
- advancing the practices of management science/operations research through seminars, workshops, discussions, and publications for the well-being of society at large;
- establishing academic and industry linkages for the application of management science/operations research tools.

MSORSM's strategies are in turn implemented through several activities, including

- to organize national and international conferences, seminars, IFORS workshops, professional talks, training modules, linkages, and collaborations with operations research societies worldwide, and linkages with industries;
- to publish newsletters, periodicals, journals, books, circulars, and information leaflets after due permission from relevant authorities;
- to give awards in recognition of outstanding academic or professional achievement in management science/operations research. These awards include Student Achievement Awards

in the following categories:

- PhD Thesis
- Master Thesis
- Master Dissertation
- Bachelor Project
- to raise funds and to accept gifts, donations of bequests with a view to furthering, either directly or indirectly, the objectives of the society.

ADMINISTRATION OF MSORSM

MSORSM is governed by an executive committee that consists of the President, Immediate Past President, Vice President, Honorary Secretary, Honorary Treasurer, two Honorary Auditors, eight at-large Council members, and a Patron. In 2009/2010 these offices are held by

- Patron: Dr. Halim Shafie
- President: Dr. Ilias Mamat
- Immediate Past President: Dr. Han Chun Kwong
- Vice President: Dr. Adnan Ahmad
- Honorary Treasurer: Mr. Liew Swee Liang

- Honorary Secretary: Dr. Adibah Shuib
- Honorary Auditors: Dr. Mohd. Sahar Sawiran and Associate Professor Hasni Hashim
- At-Large Council Members: Dr. Razidah Ismail, Mr. Amiruddin Jumaat, Associate Professor Adam Baharum, Dr. Mohd. Omar, Mr. Muhamad Shahbani Abu Bakar, Dr. Isahak Kassim, Dr. Amirudin Abd. Wahab, and Dr. Muhammad Rozi Malim

Past Presidents of MSORSM (with their terms in office) include

- 1986–1987: Dr. Han Chun Kwong
- 1988–1994: Dr. Othman Yeop Abdullah
- 1994–1995: Mr. Rodzlan Akib Abu Bakar
- 1995–1997: Dr. Han Chun Kwong
- 1997–2001: Dr. Halim Shafie
- 2001–2008: Dr. Han Chun Kwong

INTRODUCTION

Risk of harm and loss are present in many aspects of modern life, and as society and technology become more complex, there are ever more risks to manage. This article is aimed at readers who already know about managing risk, and describes issues that arise in managing a *portfolio* of risks. The terms risk and portfolio have many definitions, so working definitions are useful. The Society for Risk Analysis gives the following definition of risk: "The potential for realization of unwanted, adverse consequences to human life, health, property, or the environment; estimation of risk is usually based on the expected value of the conditional probability of the event occurring times the consequence of the event given that it has occurred." In this article, a single risk is taken to mean a possible event associated with a resulting consequence. A *portfolio* refers to a set of objects that are considered together. For purposes of discussion, there are several distinctions that may be useful. A portfolio of risks is a portfolio of possible events that may result in a portfolio of consequences of concern. There may be a portfolio of at-risk assets affected by events, thereby resulting in consequences. Importantly, the risk manager chooses a portfolio of decisions aimed at reducing risks

(and which may contribute to and complicate the portfolio of consequences).

This positioning of the article has several implications. First, while the article references problems in risk analysis and risk management that are generic and not specific to portfolio problems. It does not explore them in detail; for example, processes for involving stakeholders, and methods for assessing probabilities. Second, because it is about managing rather than just analyzing, decisions are relevant. Following Pate-Cornell and Dillon-Merrill [1], who describe the way that decision analysis overlaps with risk analysis and helps connect it to action, this article incorporates a decision-analytic perspective, rather than a purely risk-analytic perspective. Third, defining risk in terms of negative consequences, the article focuses on portfolio problems aimed at reducing risk rather than the many portfolio problems that merely involve risk (although the latter provide lessons applicable to the former). Finally, the range of portfolio and risk problems and methods found in practice is broad, and their intersection is not always well documented. Therefore, this article surveys broadly what the authors view as the relevant terrain and the general guidelines for navigating it.

Commonly, risk management is approached as efforts directed at single risks or ad hoc groupings of efforts directed at risks. Neither of these treatments explicitly considers possible interactions among projects or risks when risks stem from multiple sources. Whether a set of objects is considered explicitly as a portfolio is a choice made by whoever is considering them. Considering objects as a portfolio in this sense typically involves at least some additional effort in understanding relations involving multiple objects (risk, decision, and so on). Risks should be considered as a portfolio when risk from multiple sources must be managed in a coordinated manner. The need for coordination depends on the decisions under consideration: if the optimal decision that

Table 1. Examples of Portfolios of Risks and Risky Portfolios

Problem\ Application	Elements of Portfolio Directly Affected by Decisions	Nature of Risk	Interactions between Elements
NASA unmanned flight	Design elements	Component failure leading to system failure	Causation, shared vulnerabilities
Oil and gas	Wells, seismic tests	Failure to find oil or gas leads to lost investment	Correlation in well performance, dynamic information
Infrastructure	Structures (repair and improvement)	Failures of any part of system lead to a variety of consequences	Shared vulnerabilities, causation
Business products	Individual products, project development phases	Loss of investment, disappointment	Production and market synergy or dissynergy
Real estate	Structures, land	Small- and large-scale economic, social, and environmental conditions affect value	Virtuous and vicious cycles, supply/demand

influences one risk could change depending on decisions or events that relate to another risk, then ideally those risks would be managed as portfolio.

Portfolios of risks arise in many domains, examples of which are summarized in Table 1. In real estate, a portfolio of properties faces the risk that one or more properties may lose value [2]. These losses may correlate with common initiating events such as local economic conditions or interest rates [3]. For business product portfolios, there is a risk that a new product will fail and the money invested in its development will be lost [4]. Of course, this is a risk that can be minimized by simply not launching any new products, and in this sense, it may be better viewed as a risky portfolio of opportunities that involve risk rather than as a portfolio of risks. In the oil and gas industry, there are portfolios of opportunities involving risk in drilling expensive, unsuccessful wells at one site that correlate with those of other sites [5]. Additionally, investments in information technology can be considered as a portfolio, more so than other corporate infrastructure investments since information technology shares both financial and nonfinancial resources in a coordinated manner [6]. Critical infrastructure within a region or

of a certain type, such as dams, chemical plants, and power plants, may be viewed as portfolios of assets with an associated portfolio of risks (due to failure) and associated investments that can also be viewed as portfolios. Purely financial assets (stocks and bonds) are commonly considered as portfolios with associated risks. Large-scale engineering projects, such as those undertaken by NASA [7] may be viewed as portfolios of risks (involving multiple physical components and multiple program activities). Environmental risks may be regarded as a portfolio if shared hazards, pathways, or locations exist. In health care, a portfolio of diseases may result in a portfolio of negative health consequences (pain, death, economic costs), and can be mediated by a portfolio of treatments.

The remainder of this article will focus on approaches to portfolio risk management and best practices associated with portfolio risk management. The following sections begin by reviewing key portfolio methods and how they can contribute to a quality decision process. Continuing along the same lines, a comparison of the strengths and weaknesses of the different approaches together with a method of combining approaches is developed next. The final section illustrates risk portfolio management concepts using the

example of managing a portfolio of infrastructure risks.

APPROACHES TO PORTFOLIOS

It is useful to first consider four primary approaches to managing risk portfolios: project portfolio management (PPM), modern portfolio theory (MPT), risk analysis and risk management, and systems modeling. These approaches have different strengths, and the manager who is aware of the range of possibilities can and does select among features of each of them (or other methods) as needed to apply an integrated approach to risk portfolio management. For this discussion, it helps to characterize the approaches in terms of the generic steps of a quality decision process. According to Howard [8], a decision process has six elements on which its quality depends: framing, alternatives, information, values, logic, and implementation. These will be highlighted as they arise in the discussion of each approach.

Framing seeks to define what is to be decided and why. This often means delineating the current decision from previously established policies and future downstream decisions. Within risk portfolio management, framing comprises defining which risks are to be included within the portfolio and clarifying any portfolio constraints. The generation of alternatives ultimately creates the decision problem. A good set of alternatives is creative but feasible; in the context of risk portfolio management, alternatives are the many means of reducing the risks (either the likelihood or the magnitude of negative consequences) within the frame. Information, ideally high quality information which is relevant, correct, and complete, is necessary to make predictions. Risk portfolio management information typically pertains to individual risks. The values stakeholders and decision makers ascribe to the range of outcomes must then be determined. A logical synthesis of all of the above results in the identification and selection of the preferred alternatives. Finally, implementation of the selected alternative contributes to the realization of a desirable outcome.

The rest of this section sketches the four portfolio approaches in some more detail, together with some of their major variations. The goal here is to orient the reader but not to cover in depth all the issues that arise in practice, so many details have been left out. The last two sections consider these approaches as part of an integrated approach to risk portfolio management.

Project Portfolio Management

PPM refers to an approach that selects which projects from a portfolio of candidates should be funded in the face of a budget constraint, often utilizing decision analysis methods. In the simplest case, there are no significant interactions between projects other than competition for funds. Projects are ranked in terms of a productivity index measuring their payoff per unit of resource used. When total cost is plotted against total value for each portfolio, then the cumulative cost and value for the projects in order of productivity form an efficient frontier for the set of possible portfolios. This approach has been widely applied in industry for R&D projects, especially in the pharmaceutical industry [9], and within the government for army-base closures [10]. In its simplest form, PPM finds the optimal portfolio solving $\text{Max}_{F_i} V = \sum V_i F_i$ s.t. $\sum F_i \leq B$, where F_i denotes the funds allocated to project i , V_i denotes the value (or expected value) of project i and B denotes the available budget. At its most complex, PPM relies on sophisticated optimization tools to choose a strategy of coordinated and in some cases, dynamic decisions subject to maximization of some value measure on the distribution over possible outcomes subject to constraints describing resources, allowable interactions between actions, allowable levels on certain outcomes, laws of nature, and many other properties of a situation. Decision-support software may be useful in finding solutions.

PPM may be appropriate for managing risks under the following conditions: the only (or main) interaction between risks is that they compete for resources; the objective is to minimize the relevant measure of risk, expected loss (compared to some baseline); there is a budget constraint for investing

in risk reduction; for each risk there is a corresponding project to reduce that risk. Here, expected loss is the sum over all risks of the product of the probability that the negative outcome associated with the risk occurs and the magnitude of the outcome. The risks thus map to the project funding decisions. The alternatives in the portfolio decision problem are the levels at which to fund (if at all) efforts toward reducing each risk. PPM prioritizes the projects that reduce risk. This approach is used for business investments with some uncertainty, notably R&D. Typically, one project affects one risk. The valuation metric is typically expected dollar value or expected net present value; with portfolios of risks it may be natural to think instead of expected loss.

Consequences can take many forms, and it may be unnatural to consider only financial loss. Multicriteria methods [11,12] in PPM allow for project values (and expected values) across a range of objectives to be converted to a single score and expected value can still be used.

The portfolio is defined to include as its elements the possible activities under the funding authority, so different levels can view the portfolio differently. For example, in the pharmaceutical industry, there may be a division focusing on heart disease and the manager of this division views the portfolio as the products and compounds under development. At a higher level of the organization, an executive may think about a portfolio of business lines; for example, cancer therapies, psychiatric drugs, medical devices, generic drugs, and medical supplies.

Framing for the problem involves determining the set elements that are candidates to receive funding. The primary information needed is the cost, probability of failure, and the loss given failure (alternatively, the probability of success and the gain given success) associated with each project. If needed, interactions between projects are considered explicitly; for example, two projects may be able to share the cost of a common item, or two projects may be mutually exclusive. The decision rule that logically synthesizes all of these inputs is to select the portfolio that maximizes the measure of value, subject to the

budget constraint. If there are no interactions among risks other than their competition for funds, a good decision rule may be as simple as ranking projects in terms of a productivity index; for example, value/cost, and funding them in order until the budget is exhausted.

Portfolio Risk, Variance, and Nonlinear Loss Functions. One step in complexity beyond basic PPM is when outcomes for the elements of the portfolio interact in terms of a loss function, meaning the total loss depends on some measure of the sum of the realized consequences of the risks. If the combined loss from two risks combined is equal to the sum of the loss from each risk alone, then the *expected* loss of the two risks is equal to the sum of the expected loss for each risk alone. With a more general nonlinear utility or loss function, this is not the case. One risk might be acceptable if there are no others, but if there is already a good possibility of ending up with a significant loss, the prospect of further loss may render an additional risk unacceptable. In such cases, it is particularly important to understand the loss function/risk tolerance as there may be heuristics to manage risks based on it [13,14]. For example, such a loss function can make risk diversification strategies attractive when they reduce the likelihood of extreme downsides. This feature complicates the portfolio management approach in two ways: a loss (or utility) function must be assessed, and computation of the expected loss minimizing portfolio has a nonlinear element that may require more advanced algorithms.

One key difference between portfolios of risk-reduction efforts and portfolios of, say, R&D projects is the way we would think about variance. For the former, the expected payoff of an investment to remove a risk is equal to the expected loss avoided. This is the probability of the negative consequence occurring in the absence of the investment multiplied by the impact of that negative consequence if it occurs. In a sense, the project is “successful” and adds value in the counterfactual situation where the negative would have occurred were it not for the investment, and otherwise it adds no value. In contrast,

an R&D is successful and adds value if the technology works. If the project is not undertaken, there is no chance of it working. The variance for the value of a project in either case is the $x^2 p(1-p)$ where p is the probability of the investment being a “success” and x is the “gain” in the case of a success.

With portfolio variance, there is a key difference. In the simple case of uncorrelated elements, the variance of the value of the portfolio is the sum of the variance of all its uncertain elements. R&D managers are concerned with the variance of the payoff of R&D but with a risk portfolio, stakeholders are concerned with the variance of the results of the negative consequences. If no projects are funded, each risk contributes its variance to the total; the total variance of the risk portfolio is thus its original variance less the variance of the projects. If a risk-adjusted bang-for-the-buck ranking is used, it may be necessary to add an adjustment factor for the projects in a risk portfolio, instead of subtracting it as in an R&D portfolio. In some cases, this implies that a high variance portfolio of risk mitigation activities is desirable. This seeming paradox is due to a definition of value, whereby the project value is negatively correlated with the value of the underlying portfolio of assets.

Interactions within a Project Portfolio.

Beyond interacting due to a nonlinear loss function, risks can interact in more specific ways: risks may interact dynamically (whereby one risk leads to another).¹ Risks may interact with respect to multiple criteria so that multiattribute utility functions [16] might be suitable, especially if negative outcomes in one dimension make negative outcomes in another dimension more costly. There may be cost synergies or dissynergies or more general nonlinear relationships between efforts and risk reduction. The logical synthesis of the project level information must produce a picture of the portfolio level risk. Advanced techniques in PPM can

accommodate some such considerations by expanding value calculations for specific projects but at some point, these interactions become too numerous and complex to deal with on a project-to-project basis, and other methods are suitable for characterizing the situation and making decisions.

Interactions also present a major challenge for selecting actions within portfolio management (whether PPM or other approaches) because there can be a vast range of possible strategies involving a large number of decision variables. Combinatorial optimization (often using integer, binary, and logic programming methods) and constrained optimization methods have been successful in this regard. Contingent portfolio programming [17] has been applied to risky projects with multistage decisions and with multiple objectives incorporating risk aversion. Most computational optimization methods require well-specified objective functions; objectives can be identified and agreed upon. Robust portfolio modeling [18] can be useful where multiple objectives apply but where, as is common in portfolio problems, it is hard for the range of stakeholders to specify an exact objective function. There is quite a substantial literature on multicriteria optimization methods [19].

The example at the end of this article illustrates different types of interactions between individual risks and projects. If there is rich enough interaction between them, enumerative approaches may be impractical. When there are well-defined correlations between many risks and where it is desirable to reduce the variance of the sum of the risk outcomes, financial theory described in the next section can be useful in characterizing the portfolio.

Modern Portfolio Theory

MPT was first formalized in several well-known articles [20–23] and is now standard in finance textbooks, for example in Ref. 24. The crown jewels of MPT are elegant models resulting in simple formulas for investing under the assumption of efficient markets.

MPT is the nearly universal basis for management involving portfolios of risky financial assets, including stocks, bonds, and cash.

¹It may be possible in such cases to characterize and calculate outcome distributions based on these interactions using precedence matrices [15].

Individual assets such as stocks have uncertain returns with both upside potential and downside risk. An investment portfolio consists of a number of different assets purchased. It is common to denote as w_i the weight of asset i in the portfolio. The return on an asset i , r_i , is the percentage by which its value changes over a period of time (e.g., annual return). Arithmetic shows that the return on a portfolio is the weighted sum of the returns of the assets in it. The *expected* return on a portfolio is likewise the weighted sum of the expected returns of its assets.

Due to the diminishing marginal utility of wealth (as well due to psychology and the planning benefits of predictability), investors are generally risk averse. In market portfolios, this means that they would be willing to give up some expected return to reduce the spread of outcomes (typically measured as variance). Investors thus typically aim to achieve the maximum return for a given level of risk, or alternatively, to have the minimum risk associated with their expected level of return. For such investors, diversification is a free lunch. Variance can be reduced without affecting average return. If asset returns are uncorrelated, the portfolio variance is the sum of the product of each individual asset's variance and the square of the asset's weight in the portfolio. Then portfolio variance can be reduced arbitrarily close to zero by having many assets each with a weight in the portfolio of close to zero.

The fact that returns on assets are correlated, makes this theory more interesting. Many investment risks are essentially uncorrelated; for example, the fortunes of one company in one industry may depend on the occurrence of an unpredictable technical breakthrough, while the fortunes of another may depend on the status of international relations. The insurance aspect of pooling poorly correlated risks is the motivation for having mutual funds. Individual mutual fund investors need not be concerned with the risk associated with specific companies. Stock prices, however, are often correlated. In a strong economy, for example, most stocks tend to go up while in a weak economy they do not. The correlations are even stronger between stocks of similar

companies in similar industries. Variances and covariances of individual asset returns are estimated using a mix of judgment and sophisticated econometric methods but unfortunately, MPT models require correlations and uncertainty looking forward to the future, but automated methods can only mine historic data. From these estimates, the variance of portfolio return can be calculated based on the weights in different assets and the matrix of covariances between the assets.

As a mathematical problem, it is theoretically possible to find the variance minimizing mix of investments for any level of expected return, that is, the efficient risk-return frontier. With a substantial number of potential investments, however, finding this frontier could be a combinatorially large or even impractical problem. Fortunately, mathematical simplification is possible. The market as a whole is the sum of all assets weighted by the proportion that they represent of the market's total value. The Nobel prize-earning references above show how useful this fact is. For the purpose of constructing an efficient portfolio, it is often sufficient to summarize all the asset correlations in terms of the correlation between each asset's return and the total market return. The asset's correlation with the market as a whole is its β value (because the theory derives from statistical regression model coefficients), and the portfolio itself has a β value equal to the weighted sum of the β values of its elements. Thus correlation coefficients are a widely used and theoretically supported model simplification of multivariate probability distributions that would be difficult to assess directly.

This gives rise to the distinction between systematic and nonsystematic (sometimes called *idiosyncratic*) risk. If the market is efficient (as is often assumed in theory), there is no way to hold stocks that give the same return as the market without also at least having the risk of the overall market. That risk, which cannot be diversified away, is called *systematic risk*. In contrast, a portfolio on the efficient frontier would have small proportions of many different stocks so that the idiosyncratic risk of each asset is diversified away.

But the investor can do better than holding a mix of risky assets. A diversified index of the market as a whole is on the efficient frontier. But the investor can (in theory) also hold a “risk-free” investment, one with guaranteed return. US Treasury bills have sometimes been assumed to be risk-free in this sense. For any level of risk the investor might wish to accept, some percentage β of funds can be invested in the market portfolio and the remainder invested in the risk-free asset leaves the portfolio to leave that risk. The variance of this investment mix is β times the variance of the market portfolio. In an efficient market, the expected return on this portfolio is $(1 - \beta)r_f + \beta r_m$, where r_f is the rate of return on the risk-free rate and r_m is the return on the market. The set of possible risk-return points obtainable by choosing different levels of the risk-free investment is called the *capital allocation line*, and for each level of risk, the corresponding point on this line has return greater than or equal to the best portfolio that does not contain the risk-free asset. The value of β represents the leverage of the portfolio and could range from less than 0 (for a portfolio which actually moves opposite to the market; i.e., one in which stock is sold short in order to purchase the risk-free investment) to more than one (a leveraged portfolio). The risk appetite of the total pool of investors determines just how high r_m must be in order for there to be an equal number of buyers and sellers of risk, and MPT says that current market prices will adjust so that expected r_m is at the right level.

Finding optimal financial portfolios is by now a well- and continually studied problem. Simple algorithms often suffice, although professional investors such as hedge funds certainly have more complex and sophisticated models. These models may have constraints or value measures involving risk statistics other than standard deviation; for example value-at-risk, which gives the amount of loss associated with a given percentile. Financial engineering tools extend MPT concepts as well as options theory [25] to manage risk and return to sculpt a relatively

desirable probability distribution by diversifying across assets, diluting risks, and creating or obtaining various insurance mechanisms defined in terms of future asset prices.

Arbitrage pricing theory, a fairly recent development, allows the portfolio to be further characterized in terms of multiple “ β ” factors, each corresponding to a different systematic and nondiversifiable risk (e.g., inflation risk, real estate risk, and classic stock/bond market risk), with associated market equilibrium prices for each type of risk. This matches up nicely with applications of multicriteria decision analysis (MCDA) in finance [26,27], where alternatives are evaluated in terms of a multicriteria model and the criteria correspond to sensitivity to different kinds of risks.

MPT-based approaches can be adapted to more general decisions involving risks. Smith and Nau [28] and others have shown how in decision analysis, some risks may be treated as market-based and assigned a market-derived price while others risks must remain internal. Decision theorists [29] have identified utility functions with intuitively desirable properties that can also be characterized as simple functions of risk and return. In particular, Bell argues that $u(w) = w - be^{-cw}$ is an especially useful form when risk takes the form of a normally distributed increment to initial wealth. Such a function based on mean and variance provides a bridge from the methods and statistics utilized by financial theory (as described above) to the concerns of loss-sensitive decision making. Because utility is usually decreasing in risk, the idea of efficient risk-return frontiers may also apply to nonfinancial portfolios of actions, and some aspects of the MPT conceptual framework have been used to describe such situations [30].

To put this in terms of the decision quality framework, in MPT the frame that defines what is to be included in the portfolio is primarily the notion of correlation, that is, potential investments are considered as parts of a portfolio to the extent that the investor is concerned about their correlation or lack thereof. Risks and decisions involve available investment instruments. Where the ultimate values may be correlated,

where the level of correlation matters, and where there is some way to estimate the correlations, it is useful to consider these possible investments as the elements of the portfolio. The alternatives are best described in terms of how much of each risky entity to hold and in what overall mix. MPT typically values the portfolio solely in terms of risk (e.g., variance) and return (e.g., expected value, or expected rate of growth), and optimization formulas and algorithms logically synthesize the information with an aim to maximizing return for a given level of risk.

Risk Analysis and Risk Management

Risk analysis involves “detailed examination including risk assessment, risk evaluation, and risk management alternatives, performed to understand the nature of unwanted, negative consequences to human life, health, property, or the environment; an analytical process to provide information regarding undesirable events; the process of quantification of the probabilities and expected consequences for identified risks” [31], and *risk assessment* is “the process of establishing information regarding levels of a risk and/or levels of risk for an individual, group, society, or the environment.” Risk assessment uses a set of tools to incorporate technical information and expert judgment about the structure, likelihood, and magnitude of consequences from sets of related events. Ideally, it yields precise understanding of what drives risks and generates defensible probability distributions over outcomes from those risks under various scenarios. *Risk evaluation* (following the definition above) should aggregate information from the assessments associated with the portfolio of individual risks to develop a risk profile (e.g., a probability distribution) for the portfolio. It then relates the risk profile to the situation at hand (e.g., levels of background risk, importance of different potential losses associated with negative outcomes in various dimension). *Risk management* is the process of judging the desirability of potential consequences and selecting action alternatives, often in response to the findings of risk assessment and risk evaluation. It uses a loose set

of tools, practices, and processes, both qualitative and quantitative, that may be used with or without risk assessment. Risk management helps to ensure that there is a reasonable plan to reduce risks and that this plan is executed. The reader should note that the labels of these different activities are not always interpreted precisely and that there is overlap with other activity labels such as risk characterization and risk integration.

Risk assessment and risk management have been separated in many regulatory and planning applications. Risk assessment is considered to be a scientific evaluation process performed by scientists while risk management is associated with policy and regulatory process and is performed by regulators or planners. For example, the Environmental Protection Agency [32] specifically states that “risk assessment provides ‘INFORMATION’ on potential health or ecological risks, and risk management is the ‘ACTION’ taken based on consideration of that and other information” including, among others, economic, social, and political factors as well as stakeholder values.

In practice, this artificial separation can result in a disconnect between risk assessment and risk management. For example, the framing of problems in risk analysis is usually limited to identifying population and resources at risk and not risk management alternatives. It is generally done using conceptual models (influence diagrams visualizing relationship among stressors and resources at risk). The goal of risk assessment is not to prioritize risk management alternatives, but rather to assess risks resulting from multiple stressors and inform risk managers about these risks. Alternatives are not explicitly considered as a part of risk assessment; instead risk models are used to assess residual risks associated with implementing risk management alternatives that are developed outside of the risk analysis process.

The focus for risk assessment is collecting information and developing models to assess risk associated with potential stressors. Risk assessments usually include steps of hazard identification, exposure assessment, effects assessment, and risk characterization. Hazards are usually identified utilizing

historical data, reconnaissance site survey, preliminary models, and other available information based on professional judgment of risk assessors involved in the process. In risk assessment conducted for regulatory compliance (e.g., Superfund sites in the United States), this step also involves detailed consultations with stakeholders and regulators. Exposure assessment includes evaluation of the degree to which different population groups, environmental receptors, and resources are affected by stressors while effects assessment quantifies the level of harm resulting from exposure to stressors. Risk characterization combines results of exposure assessments and effects assessments, and compares resulting risk to regulatory benchmarks or other criteria deemed to be acceptable. Estimates and judgments related to uncertainty are part of the process, but these are rarely integrated explicitly and quantitatively during risk characterization.

Risk assessment informs risk management. Treatment of risk assessment process as “science” and risk management process as “policy” has resulted in very limited use of quantitative tools at risk management stage of risk analysis. Risk management alternatives are usually generated based on professional judgment and residual risks associated with their implementation is assessed using developed risk models. Values and other factors are incorporated in an ad hoc manner and decision analysis tools for value assessment and for logical synthesis are rarely used. Alternative selection is extensively vetted through stakeholder consultations. Implementation of selected alternatives usually requires monitoring to confirm expected reduction of risks. In many cases, though, expected risk reduction is not achievable and risk assessment needs to be repeated to meet regulatory needs [33].

In general, risk assessment treats individual risk independently and passes this information for consideration by risk managers. Sometimes simple integrated metrics are used (e.g., hazard index is developed as sum of hazard quotients for individual chemicals). In contrast to the simple portfolio problem, where the only decision variable

available to management is allocating funds to projects, risk management has a richer set of alternatives about how to manage each of the risks such as *mitigation*, *amelioration*, *diversification*, *risk sharing* (in which case, we may also be concerned with incentive effects, as in Ref. 15 as well as *establishing reserves* [34], *insuring*, or *obtaining information*, but the framework for quantitative assessment is not developed. In many cases, a single risk driver can be identified since risks, more so than project portfolios, tend to involve low probability, large magnitude events; in some cases, we can essentially ignore their interaction because of this while in other cases, their interaction is plausible enough for us to have to worry about disastrous consequences of multiple large magnitude events that overload our capacity to deal with them. Assessment of low probability events and of correlations between those events thus becomes important. If we plot resources used against the measure of risk, we obtain a risk-reduction trajectory (similar to the Pareto frontier for project portfolios).

Systems Modeling and Design

Interactions among a set of risks may be too complex and dynamic to practically capture with the approaches above. In that case, the portfolio of risks can be viewed as a system [1]. *Risk-based design* approaches are a more powerful tool for characterizing the problem structure. Dillon and Pate-Cornell describe a system for programmatic risk analysis where risks can be characterized by interactions among subsystems and components. Originally developed for NASA, their methodology divides optimization within a single project into four steps. The first identifies all viable alternatives, developing a minimum cost and residual budget for each. Next, a project-specific residual budget curve is developed which allocates the residual budget between system reinforcement and project reserves using probabilistic risk assessment. Problem scenarios are then identified together with their likelihood of developing a managerial risk profile. Finally, the components are optimized together, with risk thresholds serving as constraints, to determine if an optimal project exists.

A variation on this approach accounts for project interactions within a project portfolio. Prospects for projects dependent on previous outcomes are calculated, conditional on those previous outcomes, to form an expected project cost. Initial projects incur a cost penalty, the difference between the nonconditional and conditional cost of the later projects, for disrupting later projects. Optimization occurs to minimize the second project expected cost and to minimize the cost penalty. The framework was originally developed for sequential projects directly affected by a project failure, such as an initial space orbiter mission followed by a lander mission [35]. However, projects occurring in parallel may also be considered. Parallel risks are represented in the projects' respective fault trees; a secondary tree can be developed to show the interaction among all projects. For a range of circumstances, assessments are performed to estimate the probability of the system being in a state of failure. The tree methodology treats each node as a random variable, with arrows showing probabilistic dependence. The final node shows the probability of project failure. This approach models the interaction among projects, information acquisition possibilities, and the whole range of scenarios affecting systems, with probabilistic risk assessment.

Risk-based design incorporates risk analysis methods within the much broader discipline of *systems engineering* [36]. Systems engineering defines a system as a set of interdependent components (this set itself could be considered as a portfolio), aligned for a common objective or objectives. It is used to manage all aspects of complex projects and, therefore, could encompass an even broader notion of portfolio and of risk.

Events and consequences are quite often embedded within a system; for example, a nuclear waste remediation system [37]. Thus, it is common to bring some systems modeling tools into any of the aforementioned approaches. In even more complex settings, *dynamic systems modeling* is useful; for example understanding feedback loops may be necessary in order to anticipate emergent events. For example, it may be

that decision makers failed to anticipate the financial crisis that emerged in 2008 because they failed to take such dynamics into consideration. The global climate is an even larger system for which large dynamic models are used to gain insight about risks. The decision variables in such large systems may be a portfolio of interventions that modify feedback loops, but these are not associated in any simple manner with specific initiating events, assets or consequences. Such modeling approaches go well beyond the problem of managing a portfolio of risks and are well-detailed elsewhere [38]. Overall, managers can choose from a wide range of approaches to craft an appropriate approach to managing risk portfolios with attention to the specific challenges of the situation they face.

STRENGTHS AND WEAKNESSES OF, CONNECTIONS BETWEEN, AND CHOOSING AMONG METHODS

This section aids in selecting the right risk portfolio approach by comparing the relative strengths of the different methods and considering the type of situation in which those strengths are needed. It is helpful to start the discussion with Table 2, which summarizes (the authors' view on) the differences between the approaches described above as well as the characteristics of an integrated approach to risk portfolio management.

The different approaches have contrasting strengths and weaknesses. PPM identifies efficient allocation of resources, such as with dynamic models involving multiple resources. It tends to foster an organizational culture of efficiency too, and may explicitly encourage risk taking more than other approaches. On the other hand, although it is possible to account for project interactions, it is not simple to do so. The approach works simply when straight expected value is the decision criterion, but this may not be the case with risk portfolios.

MPT methods are quantitatively tight so that they can be used on a large scale where appropriate markets and mechanisms exist to allow for precise application of controls.

Table 2. Comparison of Approaches

Process	Project Portfolio Management	Modern Portfolio Theory	Simple Risk Analysis and Risk Management	Systems Modeling	Integrated Approaches to Risk Portfolio Management
11 Framing Factors determining what is treated as a portfolio Constraining factors	Funding authority and cycle Budget and other resources	Fungible/tradable market assets Ratios, funds available	Potential events and scenarios Acceptable risk levels, budget	Interactions between projects Acceptable risk levels, budget	Flexible Resources and performance requirements
Alternatives	Funding for each project	Percentage mix of assets	Tactics at project level	Allocating funds between projects/tasks	Look at many dimensions
Information and interactions	Required resources, probability, and value of success, <i>ad hoc</i> interactions	Return correlations and distributions, prices	Failure trees	Models of system and components	Decision-oriented interactions of various types
Values	Expected value or utility/MCDA	Risk and expected return	Acceptability based on probability of failure and magnitude of loss	Acceptability based on probability of failure and magnitude of loss	Multicriteria/utility function selected for good risk properties
Logical synthesis	Optimization to maximize portfolio-wide productivity index	Compute theoretically optimal balanced portfolios	Simulation, scenario planning	Assign optimal distribution of funding to maximize objective	Compute as needed
Implementation	Project budgets and milestones	Trades and purchases	Processes, monitoring, and responsibility	Budget development	One or more of other approaches

However, as the worldwide financial crisis of 2009 demonstrates, it tends to miss system dynamics and if conditions have changed, it may use the wrong assumptions (e.g., volatility is higher than assumed) and its decisions may not be robust in the face of such problems. Furthermore, it has not been adapted much to use beyond pure profit measures. Risk analysis and management deal especially well with uncertainty about events, as well as acknowledging the existence of ignorance. It adapts well to a system view and its processes (in theory) accommodate multiple stakeholders (as there commonly are in portfolio settings). On the other hand, risk management tools such as red–yellow–green classifications provide only a coarse prioritization. Simplistic risk management practices can be hard to translate to a specific implementation; they can lead to very (overly) conservative practices (e.g., where any probability at all of an event moves it out of the green category into yellow), and may lack sufficient quantification to identify the most optimal plan. In order to trade-off risks against benefits, MCDA approaches can again be useful.

In choosing the right tools, practitioners should match the strengths and weaknesses of different aspects of each approach to the needs of the situation. For example, certain established approaches combine two or more methods. In terms of risk measures, *value-at-risk* [39] combines from risk analysis and finance to summarize and communicate risk, making it suitable for managing certain day-to-day operations although as a management tool, it does not capture well problems involving system failure and very low probability events. *Risk-based design* combines risk analysis and systems analysis/design, and it is useful for capturing complex interactions between risks and providing a productive approach to managing risks. Programmatic risk analysis [40] combines elements of decision analysis and risk analysis in a customized approach to managing related risks. Decision analysis and risk management techniques can be combined to consider alternatives involving mitigation, amelioration, allocation, and acceptance of risks. Finally,

MCDA has been combined with risk analysis [41] to translate the range of consequences into a basis for decisions.

In an integrated approach, portfolio problems should be classified according to which tools are appropriate and then, those tools should be used. The example in the following section illustrates this idea by describing a portfolio of risks (dams and levees) and discussing how they might be managed with an integrated approach and the other approaches explained above.

RISK PORTFOLIO MANAGEMENT: APPLICATION EXAMPLE

This section uses an example from the United States Army Corps of Engineers (USACE) in order to illustrate in a specific context the general steps for managing a risk portfolio and to discuss how, within an integrated approach, different methods can be fitted to a particular problem. We note that there is no single representative portfolio in terms of the specific methods that should be used to analyze and manage it, but the idea of actively selecting methods for managing each of the various dimensions of the problem is common across portfolios. USACE and related government agencies manage thousands of dams and levees. Within the dam and levee portfolio, these agencies are responsible for allocating limited budgets to reduce the risk of failure. However, if risks between projects correlate, or if losses are not constant functions, traditional methods of allocating funding may not maximize risk reductions. Portfolio methods must then be utilized to ensure the greatest possible risk reduction in these complex circumstances. Differing elements of the previously outlined risk approaches apply in the context of dams and levees.

The methods used to support decisions about the portfolio should match the degree and type of complexities in the risks, decisions, and consequences of the portfolio and their interactions; for example, correlations among risks and nonlinear loss functions. Risk correlations occur when the likelihood and the impact of failures for different structures are not independent. Put similarly, the

loss due to two related failures may cause much greater damage than the sum of the damage caused if both failed separately. For example, a 10-ft rise in water level may be more than twice as costly as a 5-ft rise or the failure of an upstream dam may precipitate the failure of a downstream dam. Correlations thus account for the tendency of issues to change with the surrounding events. Failures may be correlated with internal or external stressors. Structures with a common design or other common characteristics could fail disproportionately in response to a specific stressor. In particular, climate change could increase the likelihood that a stressor will affect a large number of structures (sea level rise may affect structures in low-lying areas and changing precipitation patterns could have similar effects on structures in similar locations). Therefore, considerations such as diversification, system design, and dynamics could be important and could incorporate qualitative, quantitative or integrated measures of performance [42,43]. Correlations add complexity to the management of projects by instilling relationships with surrounding projects and events. Nonconstant loss functions also add complexity, as it is less intuitive to convert losses to an equivalent single dimensional value, such as monetary cost.

Managing dam and levee risks can be accomplished through both infrastructure improvements and policies/practices. Infrastructure improvements are projects that require substantial amounts of funding to put into place new hardware. These address risks to many types of structures and facilities, various groups of people, and risks from chains of events. Infrastructure improvements also ameliorate consequences ranging from loss of life to economic loss and social displacement to environmental damage. Within dam and levee management, there is a substantial but limited budget for infrastructure improvements.

Limited budgets for infrastructure improvements stimulate interest in other ways of achieving risk reduction with less financial expenditure, typically through policies and practices. Policies and practices involve zoning, organizations, and planning

for both, standard operations and contingencies. This complicated problem is surely better viewed as a portfolio than as a set of independent risks. What is done with regard to one risk can influence other risks. For example, contingency planning to open flood gates during high water events could cause downstream flooding, having the effect of exchanging dam failure risk (probability) for human risk (level of harm). A combination of policy methods and infrastructure improvements will typically be involved in most risk-reduction strategies.

Several courses of action are available to the USACE given the aforementioned considerations. The worst practice might be to fix each dam after it fails. Alternatively, a plan might be announced to perform all proposed repairs on all structures, but that plan would be unrealistic because it would likely exceed any available budget and some work would remain unfinished. Historically, engineers for each dam would write a justification for funding agencies about why they need money, and decisions about allocations would then be made through a rather unstructured political process. But if it is taken as given that the societal objective ought to be to minimize damage, that approach also has great shortcomings. USACE has recently taken steps toward more systematic decisions about these risks [44]. Dams are graded on engineering criteria (e.g., cracks, voids, spilling, concrete deterioration) and impact criteria (i.e., magnitude of consequences: potential hectares flooded, people killed, etc.) as in Ref. 45. The product of these two scores produces a prioritized list of dams (high, medium, low risk). Investment is made in the highest risk structures first. This approach imposes discipline on the process, but it may not be sufficient to allocate the available budget so as to minimize society's expected loss. It does not explicitly consider cost, so optimization algorithms cannot be applied.

PPM methods that value risk mitigation efforts can improve the effectiveness of resource allocation beyond simpler approaches that prioritize risks in terms of probability of failure or severity of failure. Where losses may be correlated, notions from financial portfolio management, MPT can be

applied. With coastal project levees, there is reason to expect losses to be correlated along various measures and returns on investments to be correlated with respect to those measures. With dams, losses should correlate with rainfall and upstream dam failures. Notions from MPT have been applied to these problems [30]. Small changes are more easily accommodated than large shifts, so there is reason for risk aversion in this kind of portfolio. This would be true—to different extents—with respect to shipping capacity, human displacement, ecological damage, etc. With the utilization of a multiattribute utility function (ideally of a form that can be expressed in terms of risk and return), one can describe portfolios with respect to each of the measures.

The purpose of the following case discussion is to illustrate how the generic steps might translate given a realistic situation, as well as to illustrate how a computational model can be incorporated. The computational model used here is a relatively simple spreadsheet. For more complex applications, a more complex spreadsheet, and a spreadsheet with Monte Carlo simulation [46] and optimization tools included in an add-in (e.g., Risk Solver by Frontline Systems, Decision Tools Suite by Palisade, or Crystal Ball Decision Optimizer by Oracle), or dedicated modeling software could be suitable.

The authors' list of generic steps (contributing to various elements of decision quality):

- Define what is in the portfolio and defining constraints (Framing)
- Define consequences of concern (Setting up to obtain information that informs values)
- Identify initiating events and emergent risks (Information)
- Structure and characterize individual risks (Information)
- Map risks to decisions about steps to reduce risk (Alternatives)
- Characterize impact of steps to reduce risks (Information bridging from Alternatives)
- Characterize cost/resources of steps (Information bridging from Alternatives)

- Characterize interactions between risks (Information bridging to Logical Synthesis)
- Calculate portfolio risk profile (Logical Synthesis of Alternatives and Information)
- Calculate portfolio risk metrics/characterizing portfolio risk (Value)
- Choose a plan (Logical Synthesis of Frame, Alternatives, Information, and Value)

In selecting the exact approach, it is useful to apply an underlying concept of decision quality. In each of the six dimensions, a 100% quality is defined as the point at which additional improvement stops being worth the additional effort required to achieve it. What this point is depends on the situation. So, while no dimension should be forgotten, it is possible to go beyond this point by doing too much analysis on some aspect of the decision. Thus, modeling structures and tools should be used that support the level of detail appropriate (generally, this is still determined subjectively) for the problem in each dimension.

The following example, using a simulated portfolio (using random number formulas in a spreadsheet to generate the parameters for each structure's condition, size, cost of repair, potential impact of failure, etc.) demonstrates how the generic steps could apply in case of USACE's management of dam and levee risks.

Define What is in the Portfolio

For this example, the portfolio set will be the dams and levees on the east coast. This selection is based partly on the charge and expertise of the USACE, but also on commonalities, concerns, consequences, and budgets shared across the projects. Also, it is unnecessary to expand the portfolio beyond this. If the goal is to manage and mitigate risk at dams and levees, including sewage processing systems or railways will not contribute to this goal. Though a greater portfolio would allow for greater resource sharing and more subtle analyses of risk, it will still contribute little to the ultimate goal of dam and levee risk reduction.

Figure 1. Drivers of portfolio value.

Define Consequences of Concern

If a dam or levee fails in part or completely, the immediate consequence is water release (in reality, there are multiple failure modes some of which have more severe consequences than others). That itself is not a problem, though downstream that water could destroy cities, homes, and habitat. The main consequences can be classified as economic, social, or environmental. Any of the structures failing would have roughly similar consequences although they would differ in magnitude. For other portfolios, it is possible only one description, financial, might be the only concern.

Identify Initiating Events and Emergent Risks

Negative consequences for dams and levees could be caused either by structural failure or operation out of specification. Operation out of specifications might result from stressed conditions such as changes in weather patterns (e.g., rainstorms). Internal causes could result from design flaws, maintenance problems, and age. In this portfolio, similar fault trees are assumed to simplify the analysis.

The logic in this simple model (Fig. 1 is that initiating events may occur (not shown in model), actions may be taken to reduce risks, outcomes for individual risks then result, and the sum of all risk outcomes determines the portfolio loss.

Structuring and Characterizing Individual Risks

In the context of the example, there must be a determination about how to judge the severity of risk. Various approaches are applicable. A simple approach might be to label dams

as low, medium, or high priority and levees as structurally sound, in need of repairs, or deficient. A second approach might be to prioritize structures based on their size or age. Yet another approach would be to classify dams and levees by the size of their downstream cities. For a PPM approach, if intuitive prioritization is not a fine enough process, one can be more precise and specify a probability of failure to capture both the condition of and the stress on a given dam as well as a numerical value for the consequence of failure, based on either a single value or multiple values such as number of displaced people and the business assets lost. In other cases, detailed fault trees might be useful. In either case, if failure probabilities are assigned, they must be defined with respect to a time period. Regardless of the method, with portfolios, it is desirable to be an honest broker by using a consistent method for all elements of the portfolio.

In Table 3, the fourth column gives the probability of failure of each dam, while the magnitude of failure consequences is shown in the sixth column.

Map Risks to Decisions about Steps to Reduce Risk

To manage the portfolio of risks, it is necessary to map the set of risks to a set of decisions. For the example the simplest mapping method was utilized, assuming that there is a single project that will completely eliminate risks for a given dam or levee. A more complicated and realistic mapping might include multiple decisions such as diverting water in addition to repairing the structure. In these more complicated situations, the model

would require entries for the different decisions and their incremental changes to probabilities and magnitudes. This could mean a much longer list of decisions with logical constraints on the decisions and mapping the interactions among decisions.

In Fig. 2, it is assumed that each project corresponds to a single reduction decision. As such, a full listing of decisions is not developed.

Characterize Impact of Steps to Reduce Risks

Steps to reduce risks can decrease the overall probability of failure, the probability of failure given an initiating event, or the consequences of failure. The anticipated decrease can then be compared against the “no action” case. The decrease in expected loss for each risk step is calculated as the difference between the original expected loss and the expected loss after the step is taken. In Table 3, it is assumed that each step reduced the probability of failure to zero. A wider selection of possible risk-reduction steps can also be accommodated. In a spreadsheet, this requires several extra columns and some additional calculations to find the impact of each step and the overall risk for any portfolio plan.

Characterize Cost/Resources of Steps

Effective management of portfolios of risks involves allocating resources effectively. For dams and levees in the example, the repair budget is the only resource under

consideration; estimating the cost associated with a given repair for a given structure is a standard engineering task. In other cases, there may be multiple resources that are limited and cannot easily be exchanged for one another; for example in a public health emergency, there may be a fixed amount of hospital beds, medical personnel and supplies, and no way to get more of one resource by giving up (or even selling) another. The amount required of each of these resources by a risk-reduction step should then be estimated.

Characterize Interactions between Risks

Characterizing risk interactions is a key and complex step. There may be interactions in terms of the likelihood of events (e.g., causation), the consequences of events, or the effectiveness of actions taken that reduce either likelihood or magnitude of consequences of two or more risks.

In the basic numerical example, it is assumed for simplicity that there are no interactions between the risks. For dams and levees, this could be true if each structure were unique and located in an entirely different geographic region. In more complex situations, risks can interact in multiple ways. Examples include the following scenarios:

- If one structure fails, structures downstream are at greater risk of failure. Sometimes this can be accommodated

Figure 2. Logic of spreadsheet model.

Table 3. A Simulated Portfolio of Risks in a Spreadsheet Model

Structure Index	Structure Size	Problem Level	Prob of Failure	Cost to Repair	Impact of Failure	Expected Loss	Variance of Loss	Exp. Loss Averted per \$	Rank	Funded?
1	3.27	4	0.13	0.56	3.57	0.47	1.46	0.04	18	0

25	11.08	2	0.17	2.83	3.13	0.52	1.36	0.18	13	0

in a spreadsheet using a precedence matrix.

- If one structure fails, it could mean that other structures with the same design are also more likely to fail. Such risk could be incorporated into a spreadsheet using joint probability or correlation tables.
- If there are dams on two rivers that join into a single river downstream, the damage caused by two dam failures together could be worse than the sum of damage caused by each one failing alone. The two dams could be modeled as a single system with multiple failure modes. The interactions of parallel or serial elements of such systems are simply modeled using logic functions.
- Some of the initiating events that contribute to failure (e.g., particularly heavy rainfall over a wide region) will affect multiple structures. This could be incorporated into the model by assigning probabilities to different initiating events and then entering probability of failure conditional on the set of initiating events. The total probability of failure would end up being the result of a calculation rather than a directly entered value.
- If the consequences of failure are uncertain, consequences could be correlated across risks. For example, a general increase in population and urban development could increase the potential cost of flooding everywhere. Such consequences could be correlated within the model.
- There are synergies in risk-reduction actions, for example if a dam and a nearby levee are fixed, it might be cheaper to do them both together than the sum of their costs if considered independently, because construction equipment will not have to be transported.

Calculating the Portfolio Risk Profile

Once all the individual risks, their interactions, and the steps to reduce the risks are

characterized, it is meaningful to look at the overall range of outcomes. A typical format for the risk profile is a probability distribution over loss. If loss is multidimensional, the risk profile could take the form of a joint probability distribution. These probability distributions can be calculated, though in general they are often simulated. In some cases, statistics (especially mean and variance, as in financial portfolios) for the distribution suffice. For example, if the family of distribution is known or if the expected loss can be calculated directly from the statistics (e.g., with a linear loss function, expected portfolio loss is by definition the mean of the distribution). These statistics can often be calculated analytically, saving the effort of simulation. Whether this works, depends on the risk measures and loss functions that are applied in the following step. Profiles may also be intertemporal, capturing risk at multiple points in time [47,48]. In the example, the expected loss across the whole portfolio, and thus the decrease in expected loss associated with a portfolio of risk-reduction activities, is simply the sum of the expected losses associated with each risk. If projects are independent, the variance of the total portfolio loss which can be calculated once assuming no reduction efforts and again, with a portfolio of reduction efforts, is similarly equal to the sum of the variance of the loss for each risk $i, p_i(1 - p_i)\text{loss}_i^2$. In cases with moderately complex correlations, variance for portfolios with correlated elements can also be calculated formulaically.

Calculating Portfolio Risk Metrics

From the risk profile, one can calculate summary statistics: the sufficient statistics above and possibly other quantities to be calculated from the profile that will feed into evaluation of plans.

For the dam and levee example, economic, societal, and environmental costs are all of concern. A total (multicriteria) damage measure could be calculated as a weighted sum of, say, hectares of habitat destroyed, number of people dislocated, and dollars of infrastructure lost. There are various methods in risk and decision analysis for estimating such trade-off weights. The marginal harm to the

area would become steeper as the magnitude of loss increases, as it becomes harder for regions to recover, so some nonlinear utility (or loss) function is appropriate.

For illustrative purposes, the numerical example here uses only a single damage measure, and a simple risk-averse utility function (for illustrative purposes only) over just one metric in terms of mean and variance where utility $u = 100 - \text{expected loss} - \text{variance}/10$. Thus, if all risk were eliminated, utility would be 100, and it is potentially unbounded on the downside.

In some situations similar to this one, there are specific guidelines to plan with regard to the worst case that has a 1/100 chance of occurring. That would be similar to a value-at-risk measure, which has been used in financial planning. The “worst case” would be the first percentile of simulation output. Alternatively, there may be some limit above which the loss becomes catastrophic, for example so much habitat disappears that coastal species go extinct. In that case, the probability that the total habitat loss exceeds some threshold amount could also be a simulation output.

It is reasonable to apply multiple criteria to the basic spreadsheet using a simple formula so that the total loss for the portfolio is a weighted sum of the loss function for economic, social, and environmental factors. More sophisticated multiattribute utility functions are still relatively simple to compute with formulas that take attribute measures as inputs but using them requires careful encoding of value judgments.

An appropriate utility function for decision-making uncertainty must reflect the decision maker’s/stakeholder’s preferences as follows: the expected utility for one risk profile is higher than that for another if and only if the decision maker prefers the first risk profile to the second. In risk situations, there may be no single clear decision maker and hence no single utility function can be entirely appropriate [49]. In that case, simpler and/or more robust measures could be used such as outranking-based multicriteria decision analysis methods, or analysis using a range of utility function parameters. Recommendations may not vary much over

the range of possible weightings. If they do, these results can still be informative for some further political process needed to ultimately choose priorities.

Choosing a Risk Management Plan

Once the portfolio level measure can be calculated for any plan, the optimal plan must be selected. The gold-standard approach is mathematical programming or optimization about which there are many textbooks [50] to find the values of decision variables that maximize or minimize an objective function subject to a set of constraints. For risk portfolios, the objective could be to minimize the expected value of the loss function or to minimize the probability that loss will exceed some level. The objective could involve one dimension or multiple dimensions. Decision variables typically allocate resources to activities or investments, but could also include scheduling and timing of efforts. Constraints typically include the available resources, but can also include policy constraints such as the probability of losses exceeding x cannot be greater than $y\%$. Constrained and combinatorial optimization methods range from the relatively simple to the highly sophisticated, requiring extensive data collection for inputs and extensive efforts at formulation. If optimization proves difficult, the choices are to simplify the model or to bring in a professional with special expertise in optimization methods.

For the simple dam case as developed here that ignores interactions between risks, optimization is relatively straightforward and does not require search algorithms. In the basic case where the objective is simple expected loss and the constraint is a monetary budget, it works to rank projects in terms of a productivity index: expected loss avoided per dollar of investment and to select the top-ranking projects up to the point that the budget is expended. The same method works if the loss associated with a failure is defined as the weighted sum of losses in each of the three dimensions, in which case the expected value of that weighted sum is used

Table 4. Portfolio Results under Different Prioritization Rules									
Criterion for Funding	Do Nothing	Arbitrary Choice	Structure Size	Problem Level	Probability of Failure	Cost to Repair	Impact of Failure	Expected Loss	Expected Loss Averted per Dollar
Cumulative cost	0.00	9.86	9.70	9.77	8.94	9.26	9.13	8.14	9.94
Cumulative value	0.00	11.64	12.50	10.06	18.78	11.57	18.77	24.26	26.61
Expected loss	36.47	24.83	23.97	26.41	17.68	24.89	17.70	12.21	9.85
Final variance	290.89	203.55	184.59	210.77	151.35	198.40	74.38	80.84	49.65
Expected loss averted per dollar	0.00	1.18	1.29	1.03	2.10	1.25	2.06	2.98	2.68
Utility = $100 - E(\text{Loss}) - \text{Var}/10$	34.44	54.81	57.57	52.51	67.18	55.27	74.86	79.70	85.18

as the numerator of the productivity index.² If the utility function uses expected loss and variance only, a heuristic that modifies the investment's productivity to account for its impact on variance may suffice. Otherwise, a fairly simple binary search method will find the optimal portfolio.

Table 4 shows the expected loss, variance, and the other calculated measures under different prioritization rules. The columns labeled "do nothing" and "arbitrary choice" are included to give a baseline of what happens when there is no strategy, for the purpose of comparing the impact of the other strategies. Funding choices change with different rules, and as rules better approximate the maximization of portfolio utility, funding choices tend to converge toward what a gold-standard decision analysis would recommend. It is less helpful to rank choices on the basis of benefit-related characteristics that are correlated with cost in predictable ways. For example, structure size and cost are correlated, so there is no benefit to choosing either large structures—whose repair cost tends to be high, or low-cost repairs—which tend to impact only smaller structures.

Ranking projects in terms of the impact of failure or the probability of failure leads to a substantially better portfolio; ranking in terms of expected loss combines both of these factors and leads to still more improvement, and best of all by a significant margin it uses the productivity index, expected loss averted per unit of cost. For all of these better rankings, there is not a great difference in which projects are funded. Ranking with multiple criteria is not shown here but the

implementation and implications are similar. If projects share initiating events, correlated responses, or causal interdependencies, the projects would start with a similar model with additional interactions structured to calculate the consequences for the set of individual risks. Simulation results could then be used to estimate the distribution of outcomes by which potential portfolios are valued. Note that correlations would typically be entered in the simulation tool itself, for example in specifying distributions for a cell and if necessary specifying correlations between various cells. It is possible to do this within a spreadsheet, for example by using a common random number as input to formulas for different cells, but such an approach is often unwieldy.

SUMMARY

This article has described what makes a set of risks worth considering as a portfolio and how decisions about managing that portfolio of risks can be structured and executed. Some sort of quantitative modeling is almost always needed. Significant gains come just from recognizing portfolio management as an optimization problem, that is minimizing the expected value of the loss function by choice of risk management decisions subject to a resource constraint. Depending on the characteristics of the portfolio of risks and the potential actions to reduce them, different modeling approaches can be used. Simpler approaches have the benefit of taking far less time to perform and explain, but if they are too simple, they ignore important interactions between risks. This can lead to underestimating the remaining portfolio risk or overlooking ways to eliminate more risk with a fixed budget, or otherwise getting the wrong answer. The specific theoretical approaches described in this article are well documented elsewhere in risk analysis, finance, and operations research. The reader should use this article as a guideline for identifying an approach and the steps to plan for it, and to access the referenced literature for in-depth assessment and modeling guidelines.

²Although appealing in its simplicity, the use of productivity indices can have substantial limitations. A single productivity number can more easily reflect cost efficiency than cost effectiveness, and may be insufficiently sensitive to context in cases where effectiveness differs from efficiency. Examples include dealing with uncertain costs, multiple resource constraints, multistage decision processes, synergies or dissynergies across expenditures, large discrete expenditures that must be coordinated within a fixed budget, or nonfixed budgets.

This article has focused on assessment and modeling approaches for managing risk portfolios. There are certainly other related issues to keep in mind. To implement decisions, for example, requires a variety of managerial and relationship skills. It is surely helpful to have transparency in the process so that stakeholders understand the process and believe it to be fair and valid. The process itself may involve oversight, quality controls, and participation of key experts and decision makers. It can be helpful to question the robustness of models. This means asking what happens to the decisions if assumptions about key relationships or parameter values are wrong. Sensitivity analysis techniques are a good starting point for this. Such steps can both, protect against oversights and errors in analysis and create some of the trust required for implementation. Finally, implementation of efforts to reduce risk often involves handing over of responsibility to engineering and project management professionals. Careful definition and documentation of exactly which alternatives affect which risks, to what degrees, at which times, and with which resources will facilitate a smooth hand over.

Although explicitly managing a set of risks as a portfolio is more complicated than managing them merely as a series of individual risks, it is often still worth the additional effort. In such diverse domains as financial management, product development, and military procurement, portfolio management tools have been explicitly adopted even to the point where there is a high level job with the title "portfolio manager." Risk managers have long been managing implicit portfolios of risks, and they can productively incorporate a variety of portfolio management techniques.

MANAGING CORPORATE MOBILE VOICE EXPENSES: PLAN CHOICE, POOLING OPTIMIZATION, AND CHARGEBACK

SAMUEL S. CHIU
Department of Management
Science and Engineering,
Stanford University,
Stanford, California

INTRODUCTION

Mobility communication management spans the spectrum of user choice, device procurement/inventory/replacement, IT security, corporate policy compliance, usage monitoring, expense optimization, and billing. Today, there are many vendors providing a subset or the full spectrum of such mobility communication management services to corporate customers, a service collectively (perhaps not quite accurately) known as TEM, *telecom expense management*. The focus of this article is on mobile voice expense optimization. A (stand-alone) mobile voice subscription plan, which is readily available to a consumer, can generally be characterized by three parameters: monthly recurring charge, monthly (peak) minute allowance, and per minute overage charge, denoted by the triplet (F, B, δ) , a fixed charge, a block of minute allowance, and δ per minute if the monthly peak usage exceeds B . An (stand-alone) individual user has to decide which plan to choose: too large a base plan will result in unused wasted minutes, while too small a plan will incur expensive overage charges. Similar to family plans, a corporation has different pooling options. A pooling plan allows subscribers in the same pool to share a common pool of minutes. An overage results when the collective usage exceeds the common pool of minutes. We examine the mathematics behind pooling and how to create the best

pooling arrangement minimizing mobile voice expenses. Depending on the options chosen (or often negotiated between a corporation and its mobile carrier), the mathematics can become quite challenging. It turns out that the most complex combinatorial optimization pooling problem can be efficiently and effectively solved using a column generation technique. We provide case studies to illustrate the potential (and actual savings) for the stand-alone plan choice decision as well as the collective pooling optimization; typically resulting in 20–30% of annual savings, which translate into tens of millions of dollars for large corporations. A very important, often a stumbling block to implement a pooling solution, aspect of pooling is *chargeback*—how to allocate monthly pooled expenses to individual accounts (which often belong to different units in an organization). We share with you a simple and equitable chargeback scheme which is well received and readily implemented by corporate clients.

Column generation techniques likely trace its origin to Ford and Fulkerson [1] and Dantzig and Wolfe [2], while Gilmore and Gomory [3] specialize this decomposition principle to the cutting stock problem. Barnhart [4] and Moretti *et al.* [5] provide excellent literature background on this subject. This article focuses on the application of this technique to a real-world problem with its main contribution in problem formulation, turning a seemingly intractable combinatorial optimization program into a manageable problem, which results in substantial savings, both in absolute and percentage terms.

We first introduce notations to define our optimization problem: the input parameters, available data and, most importantly, formulating an objective function. Once we are able to evaluate the objective function of one's decision, we turn to the issue of optimizing. In one instance of our optimization problem, it becomes necessary to reformulate the problem to allow for a tractable

solution approach. We illustrate our problems with many examples, concluding with an actual case study illustrating the benefit of optimization.

PRELIMINARIES: INDIVIDUAL USAGE PATTERNS AND SUBSCRIPTION PLANS

We define various terms and parameters in this section.

USER SPECIFIC PARAMETERS:

- N number of users
- i user index, $1 \leq i \leq N$
- $\mathbf{m}_i^m$ minute usage for user i in month m , a random variable
- $\mathbf{m}_i$ $\mathbf{m}_i^m$ is independent and identically distributed (iid) with distribution $\mathbf{m}_i$
- μ_i monthly mean (peak) minute usage for user i , expectation of $\mathbf{m}_i$
- σ_i standard deviation, SD, of $\mathbf{m}_i$

SUBSCRIPTION PLAN SPECIFIC PARAMETERS:

- K number of available plans
- k plan index, $1 \leq k \leq K$

- F_k monthly fixed cost (also known as MRC, *monthly recurring cost*) for plan k
- B_k monthly peak minute allowance for plan k
- δ_k per minute overage charge when monthly usage is above B_k for plan k

A usage pattern (or profile) is represented generally by a distribution of the random variable $\mathbf{m}$, with mean-SD pair (μ, σ) . Plan k is represented by the triplet of plan parameters (F_k, B_k, σ_k) .

It is instructive to graphically view the total (monthly) cost of each of the six plans as a function of usage, superimposed by several usage patterns (Figure 1). For illustration simplicity, we use a normal density function to represent a usage pattern. It turns out that the issue of negative usage (of a normal random variable) can be explained away; this will be addressed after the derivation of Equation (2).

- Each plan has a fixed MRC up to its monthly allowance. Usage above the allowance will incur a linear cost shown as the slope of the two-part tariff.

Table 1 shows four usage patterns

Figure 1. Plan and usage profile.

Table 1. Usage Pattern/Profile (μ, σ)

	μ	σ
A	800	190
B	1750	200
C	1750	600
D	3800	800

- Usage patterns *B* and *C* consume the same peak minutes on the average while pattern *C* has a higher usage variation. It is, perhaps, intuitive that usage *C* may benefit from subscription to a higher plan (e.g., Plan 5) since this user routinely exceeds the allowance of Plan 4 even though its average usage is below Plan 4's allowance. Usage pattern *B* rarely exceeds the monthly allowance of Plan 4, thus the appropriate (best) subscription is likely to be Plan 4.

We define $\text{Cost}[m; (F, B, \delta)]$ as the monthly cost when m minutes are consumed under a plan with parameters (F, B, δ) . We note that the usage m has the distribution of $\mathbf{m}$.

$$\text{Cost}[m; (F, B, \delta)] = F + \delta \max(0, m - B). \quad (1)$$

MODEL FORMULATION

Modeling Usage Distribution and Cost Function

The following observations can be made after the examination of many individual usage patterns.

- Unlike personal users, corporate liable account users do not *watch* their minutes toward the end of the month: to be more frugal if current usage is near (or has already exceeded) the allowance.
- There are slight seasonal fluctuations over the course of a year (e.g., Christmas and Thanksgiving), but they are not

significant—again quite distinct from a personal account.

- Most users follow a rather stable usage pattern when they stay on the same job with similar responsibility.
- The usages of different users can be reasonably assumed to be independent.
- It is generally, but not always, true that the higher the average usage, the higher the variability (i.e., standard deviation of usage).

Given these observations, it is appropriate to use expected cost as the minimizing objective when a user is to choose the best plan (least cost over the long run). In order to evaluate the expected monthly cost of a user, one needs to choose a usage distribution of $\mathbf{m}$. There are many choices of distributions with parameters chosen to fit usage statistics (e.g., the mean and standard deviation of monthly usage). We have considered various distributions (e.g., normal, triangular, and trapezoid) and found that the exact choice of distribution generally does not impact the optimal plan selection, while the mean and standard deviation of usage play an important role. We eventually choose the normal distribution to represent a usage pattern by matching its mean and standard deviation from historical usage data.

Computing Usage Mean and Standard Deviation

For each user, we compute the mean and standard deviation of monthly usage if enough history is available. The mean and standard deviation will be updated each month to incorporate new usage data. A new user's statistics have to be estimated, either by a three-point triangular distribution (minimum, most likely, and maximum usage, via questionnaire) or using the *average* of the user base.

Computing the Average Monthly Cost

The following formulae are used to compute the monthly usage cost for each subscriber, based on their usage statistics (or usage profile) and plan parameters. It is an exercise in

integration (by parts) using the normal distribution and the two-part tariff of Equation (1).

$$\begin{aligned}
C[(\mu, \sigma); (F, B, \delta)] &= \int_m \text{Cost}[m; (F, B, \delta)] f_m(m; \mu, \sigma) dm \\
&= \int_{-\infty}^{\infty} F f_m(m) dm + \delta \int_{m=B}^{\infty} (m - B) f_m(m; \mu, \sigma) dm \\
&= F + \frac{\delta \sigma}{\sqrt{2\pi}} e^{-0.5z^2} - \delta \sigma z [1 - \Phi(z)]. \quad (2) \\
z &= \frac{B - \mu}{\sigma}, \\
f_m(m; \mu, \sigma) &= \frac{1}{\sqrt{2\pi}\sigma} e^{-\frac{1}{2} \left(\frac{m - \mu}{\sigma} \right)^2}, \\
-\infty &< m < \infty, \\
\Phi(t) &= \frac{1}{\sqrt{2\pi}} \int_{-\infty}^t e^{-0.5x^2} dx.
\end{aligned}$$

To derive Equation (2) regardless of usage a flat MRC will be charged (in addition to overage, if any) accounting for the first term in Equation (2). Therefore, *negative* value of the normal random variable impacts the calculation only in the probability that usage will be below the monthly allowance B and not on the exact distribution of the chosen random variable. As discussed earlier, we have considered various distributions (e.g., normal, triangular, trapezoid) and found that the exact choice of distribution generally does not impact the optimal plan selection, while the mean and

standard deviation of usage play an important role.

RIGHT SIZING

Find the plan that will minimize a usage pattern (μ_i, σ_i) with plan choices (F_j, B_j, δ_j) , and $1 \leq k \leq K$.

$$\begin{aligned}
\text{Min}_{1 \leq k \leq K} C[(\mu_i, \sigma_i); (F_k, B_k, \delta_k)] \\
= C[(\mu_i, \sigma_i); (F_{k_i^*}, B_{k_i^*}, \delta_{k_i^*})] \equiv C_i^*. \quad (3)
\end{aligned}$$

In words, plan k_i^* is the expected cost minimizing plan for user i , leading to optimal expected cost C_i^* .

It is our experience that the optimal plan is robust in the choice of distributions (normal, triangular, trapezoid) when we match a user's mean and standard deviation of minute usage with historical data.

Because of incentive conflicts, the plan (originally) recommended by a carrier's sales representative is (almost) always not the least cost option for the user. The savings due to right sizing are in the 10–25% range.

A Numerical Example

Table 2 shows an example of the right-sizing calculation with seven users and six available plans. The expected monthly cost is calculated using Equation (2), showing the impact of the user profile pair (μ, σ) on the optimal plan choice: a smaller average usage does

Table 2. Right-Sizing Examples

		Available Plans						Best Plan

Figure 2. Pooling benefit zones.

not always favor a plan with smaller minute allowance.

POOLING CONCEPT

A pooling plan allows subscribers in the same pool to share a common pool of minutes. An overage results when the collective usage exceeds the shared pool of minutes. Figure 2 shows the benefit of pooling for two users with respective allowances B_1 and B_2 . When the monthly usage (m_1, m_2) is in the pooling zone, there will be no overage charges in a pooled environment as the pooled allowance equals $B_1 + B_2$. On the other hand, overage will incur in these two pooling zones under separate individual subscription plans.

We examine two pooling schemes in this article: total pooling and bucket pooling.

TOTAL POOLING

The specifics for total pooling are:

- N users $\{(\mu_i, \sigma_i)\}_{i=1}^N$ and K plans $\{(F_k, B_k, \delta_k)\}_{k=1}^K$.
- N plans are to be selected for the pool: number of plans = number of users.

- There will be a monthly pooling fee, f , for each user in the pool, considered as a feature fee.
- The total usage $\mathbf{M} = \sum_{i=1}^N \mathbf{m}_i$ assumes a normal distribution with mean and standard deviation computed as $(\mu_M, \sigma_M) = \left(\sum_{i=1}^N \mu_i, \sqrt{\sum_{i=1}^N \sigma_i^2} \right)$.
- The pool will collectively subscribe to n_k plans of type k , with pooled parameters defined as $(F^P, B^P, \delta^P) \equiv \left(\sum_{k=1}^K n_k F_k, \sum_{k=1}^K n_k B_k, \frac{1}{N} \sum_{k=1}^K n_k \delta^k \right)$.
- The constraint on $\{n_k\}_{k=1}^K$ is $\sum_{k=1}^K n_k = N$.

The total pooling optimization problem becomes

$$C_{TP}^* \equiv Nf + \underset{\{n_k\}_{k=1}^K, \sum_{k=1}^K n_k = N}{\text{Min}} C[(\mu_M, \sigma_M); (F^P, B^P, \delta^P)]. \quad (4)$$

We will not provide details to solving this integer programming problem, except that the optimal pool cost (including the monthly feature fee Nf) is substantially below the sum of the individually optimized plans—showing the benefit of pooling. We delay our numerical example presentation till the last section where we provide details of a case study.

CHARGEBACK

If a user is in a plan by himself, he/she (or his/her department) will be responsible for all its charges. In a pooled environment, how should the collective cost be charged back to each user account? For example, if the pool incurs a cost of \$10,000 and a (peak) usage of 100,000 min, should a user pay proportionally to his/her usage, at \$0.1/min? The answer is no. Such a proportional chargeback scheme would imply that everyone will be paying for his/her average usage over the long run, which does not differentiate between users with different degree of usage variations. Consider two usage profiles (μ, σ_1) and (μ, σ_2) with $\sigma_1 \gg \sigma_2$. Results of right sizing would likely return a larger subscription plan for user 1 providing a larger cushion to avoid

likely overage charge. It is arguably fair to charge user 1 more even when these two users consume the same number of minutes in a given month. The following chargeback scheme is proposed and implemented:

- Right size user j resulting in optimal plan k_j^* with $(F_{k_j^*}, B_{k_j^*}, \delta_{k_j^*})$.
- If user j consumes m_j minutes, use Equation (1) to calculate his/her cost as if he/she were subscribing to his/her optimal stand-alone plan: $C_j = \text{Cost}[m_j; (F_{k_j^*}, B_{k_j^*}, \delta_{k_j^*})] = F_{k_j^*} + \delta_{k_j^*} \max(0, m - B_{k_j^*})$.
- The total “artificial” charge is: $C = \sum_{j=1}^N C_j$. However, the actual invoice to the pool, denoted as PC, should be lower than C ; resulting in a total pool benefit of $PB = PC - C$. We note that there is no guarantee that PB will be positive, but we have not experienced otherwise in many years of pooling.
- PB will be distributed back to the user proportional to their spend: $PB_j = \frac{C_j}{C} PB$.
- Each user will be paying less than subscription to the best stand-alone plan.

This chargeback scheme is well received by corporations because it shows the benefit of pooling when each user is paying less than what he/she can do optimally on his/her own. There are other variations on this chargeback scheme, which we will not detail here.

BUCKET POOLING

This is by far the most interesting pooling scheme, which naturally uses the column

generation technique. Our contribution is mainly in the formulation of the optimization problem, from a seemingly intractable combinatorial optimization to a manageable problem with pleasing interpretation. We will first specify the rules of bucket pooling.

- There are L “bucket” plans, each with a triplet of parameters. These plans are usually larger in size (in the monthly charges as well as allowances).
- One can place any number of users in one of these bucket plans for a per user fee g . The total feature fee equals g times the number of users in a plan, minus one—the *primary* user of each bucket is not charged a feature fee.
- Users in a bucket will share the minute allowance for that bucket, with overage being charged as a per-minute cost when all bucket minute allowances are collectively exhausted.
- Every user is assigned to exactly one bucket, shared or unshared.

A moment’s reflection should convince the readers that this is a rather challenging combinatorial optimization problem. Table 3 shows an example with partial plan assignments to highlight its complexity. There are 1000 users to be assigned to five available bucket plans, each with its respective plan parameters. For examples, users 5 and 7 share the #1 plan, while user 8 is all by herself subscribing to plan #2. Once each user is assigned to a plan, we use the evaluation formula (2), with additional line charge fees, to compute the expected cost of such a user grouping; and to eventually seek the optimal grouping. We will not know *a priori* how

Table 3. Sample Bucket Pooling Assignments

	Monthly (\$)	Minutes Allowance	Overage (\$/min)	Additional Line Fee (\$)	Assigning Users	Total Line Fee (\$)
Plan 1	89.99	900	0.40	5.00	5, 7	5.00
Plan 1	89.99	900	0.35	5.00	3, 12, 28	10.00
Plan 2	99.99	1200	0.35	5.00	8	0.00
Plan 3	134.99	2000	0.35	5.00	11, 25	5.00
Plan 3	134.99	2000	0.35	5.00	6, 13, 20	10.00
Plan 4	179.99	3000	0.35	5.00	10, 15, 17	10.00
Plan 5	250.00	5000	0.30	5.00	1, 2, 4, 9	15.00

many plans (and of what kind) will be used and how many (and who) will be assigned to each plan.

To reduce such assignment complexity, we seek to classify all users into a small number (between 10 and 20) of *types* (indexed by t), each characterized by its common mean and standard deviation pair (μ_t, σ_t) . We now say a few words about our clustering effort since the focus of this article is on the application of column generations technique. Clustering users into types is, perhaps, the most important contribution/observation of this article because this formulation allows an efficient algorithm to solve this complex combinatorial optimization problem with demonstrable benefit in a real-world application.

The eventual optimal “bucketing” will tell us how many users of what type will be assigned to what plan.

We view our clustering effort as a location–allocation problem on a two-dimensional Euclidean (μ, σ) space:

- Locate T points on the (μ, σ) plane, each with coordinate (μ_t, σ_t) . View these T points as centroids.
- Allocate each of the N users, each with its own mean and standard deviation pair to its closest centroid (using the Euclidean distance) to form N clusters.
- Find the location of the new centroid for each of the clusters by minimizing the sum of the distances of the cluster members to the “optimal” centroid.
- Repeat until there is no change in the locations of the centroids in the location step, reaching a fixed point.

The following notes are in order:

- The location-allocation procedure is a heuristic: the terminating fixed point depends on how one chooses the initial T anchoring centroids. Since the procedure is relatively fast, we examine several starting points and choose the least cost one.
- We use the Weiszfeld algorithm to solve the location problem for each of the clusters [6–9].
- Figure 3 is a scattered plot showing the diversity of these user profiles (μ, σ) for more than 15,000 users. Note that there are really no natural clusters dividing these users.
- Our intent is to establish “good enough” clusters, where the (μ_t, σ_t) centroid coordinates provide diversity in their values to cover the usage profiles (range) of all the N users. The centroids (μ_t, σ_t) of these T clusters cover

Figure 3. Diversity of usage profiles (μ, σ) .

large/medium/small values in terms of the mean and standard deviation of monthly usage.

It turns out the bucket pooling option is not as cost effective for a corporation, both in terms of savings and the ease to optimize/manage/monitor. The total pooling option is simpler to optimize/monitor/manage and it benefits more from the mathematics of probability: the mean of the sum (of independent random variables) grows linearly with the number of users, while the standard deviation of the sum grows as the square root (of the number of users). The cushion (or buffer) needed to avoid overage charges in a pooling environment is much less (on a per user basis) for the total pooling option.

We now introduce the following definitions and notations:

- N Total number of users to be classified into T types.
- (μ_t, σ_t) Usage mean and standard deviation of user type t , $1 \leq t \leq T$, which is the centroid location of each cluster.
- n_t Number of users of type t , with $\sum_{t=1}^T n_t = N$.
- L Number of available bucket plans.
- l Plan index, $1 \leq l \leq L$.
- (F_l, B_l, σ_l) Plan parameter for bucket plan l .
- V^j User (column) vector, $V^j = \{v_{tj}\}_{t=1}^T$, a column vector with each vector element v_{tj} representing the number of type t users in this user vector V^j . For example, $(3, 0, 0, 1, 0, 0)$ has three users of type 1 and one user of type 4 to share a single bucket plan when there are six user types. A user vector will be assigned to the least (expected) cost bucket plan.
- Y_{V^j} Number of users in V^j , $Y_{V^j} = \sum_{t=1}^T v_{tj}$.
- (μ^j, σ^j) Mean and standard deviation of usage for user vector V^j . $\mu^j = \sum_{t=1}^T v_{tj} \mu_t$, $\sigma^j = \sqrt{\sum_{t=1}^T v_{tj} \sigma_t^2}$.

C_j^l Expected cost of user vector V^j under bucket plan l .

$$C_j^l = (Y_{V^j} - 1)g + C[(\mu^j, \sigma^j); (F_l, B_l, \sigma_l)],$$

using Equation (2). (5)

C_j Least cost for user vector V^j ,

$$C_j = \min_{1 \leq l \leq L} C_j^l. \quad (6)$$

Note that we have assumed the independence of usage of each user in calculating the mean and standard deviation of minute usage for a user vector. Suppose we are able to generate all user vectors $\{V^j\}_{j \in J}$, we can succinctly write our decision problem as follows.

Bucket pooling optimization (BPO) problem:

$$C_{BP}^* = \text{Min} \sum_{j \in J} C_j x_j$$

$$\text{BPO : s.t. } \sum_{j \in J} v_{tj} x_j \geq n_t, \quad t = 1, 2, \dots, T$$

$$x_j \text{ are nonnegative integers, } j \in J. \quad (7)$$

Each user vector V^j represents a candidate bucket (choosing the least cost plan with a bucket cost C_j) consisting of users possibly from all the user types. The optimal solution to BPO specifies that x_j^* copies of user vector V^j will be purchased to cover all the users. The objective function coefficient represents the best cost value for that particular user vector selected from all bucket plan choices. The inequality constraint t requires that all type t users are assigned to a bucket. A user vector is termed *active* when $x_j^* > 0$.

This problem formulation is identical to the (zero-dimensional) cutting stock problem. It is zero-dimensional because there is no constraint(s) on how many users can be packed into a bucket plan. Instead, the cost coefficient, using Equation (6), will price out a user vector if this user vector is too expensive. We note that this is a linear integer programming problem since the cost coefficient absorbs all information about a user

vector into a constant C_j . The challenge is to generate all the (distinct) user vectors. We will use BPO-LP to represent the LP relaxation of Equation (7) without the integrality constraint, and labeled as (7-LP). We make the following observations about this optimization problem:

- In this formulation, the plan parameters are not present. Given a user vector V^j , the least cost plan will be selected using Equations (5) and (6) resulting in the cost coefficient C_j .
- The number of such user vectors is, putting it mildly large. Therefore, it is not practical (or feasible) to generate all.
- Since there are only T constraints, the number of *active* user vectors will be small (about T if we solve our optimization problem as an LP relaxation, BPO-LP).
- Column generation technique is an obvious candidate for solving this problem, given that only a very small number of user vectors will be active. Column generation considers only the user vectors (or columns) that are attractive candidates to become active.

Solving the LP relaxation of BPO as in (7-LP): LP-BPO

We denote the optimal objective value of LP-BPO as C_{LP-BP}^* and note that $C_{LP-BP}^* \leq C_{BP}^*$ because LP-BPO is a relaxation of BPO, without the integrality constraint.

The optimality condition for LP-BPO requires that the reduced cost for each x_j to be nonnegative:

$$C_j - \sum_{t=1}^T \lambda_t v_{tj} \geq 0, \quad \text{for all } j \in J, \quad (8)$$

$\Lambda = \{\lambda_t\}_{t=1}^T$ are the shadow prices associated with $\sum_{j \in J} v_{tj} x_j \geq n_t, 1 \leq t \leq T$, the constraint of LP-BPO.

In the spirit of the simplex method, the column generation technique can be verbally expressed as follows:

Start with a basic feasible solution of LP-BPO.

- We examine the reduced cost to identify non-basic variables as a candidate to enter the basis.
- If all reduced costs are nonnegative, we have an optimal (LP)solution to LP-BPO.
- If the reduced cost of some non-basic variables are negative. We pivot them to arrive at a new basic feasible solution.
- Repeat.

Instead of working with the full set of user vectors, the column generation technique seeks to generate attractive columns iteratively by solving a series of restricted master problems (LP-BPO without all the user vectors) and subproblems (each generating an attractive user vector with negative reduced cost, if one exists) using the (optimal) dual variables from the current restricted master problem.

Restricted Master Problem

Suppose we only have a subset of the user vectors $S \subseteq J$, we define a restriction of (LP-BPO) as follows, which will be referred to as a *restricted master problem*:

$$C_{LP-BP}^*(S) = \text{Min} \sum_{j \in S} C_j x_j$$

LP – BPO(S) :

$$\text{s.t.} \quad \sum_{j \in S} v_{tj} x_j \geq n_t, \quad t = 1, 2, \dots, T. \quad (9)$$

We note that $C_{LP-BP}^* \leq C_{LP-BP}^*(S)$ since LP-BPO(S) is a restriction of LP-BPO with less columns (user vectors) being considered in its solution. The optimal dual variables of LP-BPO(S), denoted as $\Lambda(S) = \{\lambda_t(S)\}_{t=1}^T$, will be used to generate additional columns to be used in a new (augmented) restricted master problem.

Subproblem. Consider input dual variables $\Lambda(S) = \{\lambda_t(S)\}_{t=1}^T$, optimal output $U^*(S) = \{u_t^*(S)\}_{t=1}^T$.

$U^*(S)$ is a candidate user vector (column) to be included in an augmented restricted master. In words, a subproblem asks: if there exists a user vector with a negative reduced

Figure 4. Flow chart: column generation to solve LP-BPO.

cost relative to the current basic feasible solution of the restrictive master problem? We note that each subproblem is associated with bucket plan l , with $l = 1, 2, \dots, L$. The optimal objective value of each subproblem represents the smallest reduced cost achievable using the current basic feasible solution in the restricted master LP.

$SP_l[\Lambda(S)] :$

$\Omega_l^*[\Lambda(S)]$

$$= \min_{\{u_t(S)\}_{t=1}^T} C_l[U(S)] - \sum_{t=1}^T \lambda_t(S) u_t(S)$$

$\{u_t(S)\}_{t=1}^T$ nonnegative integers,

$$C_l[U(S)] = [M - 1]g$$

$$+ C[(\mu, \sigma); (F_l, B_l, \delta_l)],$$

$$M = \sum_{t=1}^T u_t(S),$$

$$(\mu, \sigma) = \left(\sum_{t=1}^T u_t(S) \mu_t, \sqrt{\sum_{t=1}^T u_t(S) \sigma_t^2} \right). \quad (10)$$

Table 4. Bucket Pooling Example: User Types

User Type	μ	σ	# of Users
1	180	306	200
2	250	225	150
3	700	625	120
4	750	375	100
5	1000	500	150
6	2500	500	230
7	2500	1250	50

The cost $C_l[U(S)]$ consists of the feature fee $[M - 1]g$ and the usage associated cost $C[(\mu, \sigma); (F_l, B_l, \delta_l)]$ evaluated using Equation (2). M is the number of users in this particular user vector (or bucket assignment).

If $\Omega_l^*[\Lambda(S)] \geq 0, \forall 1 \leq l \leq L$, we have reached an optimal solution for LP-BPO—the reduced cost for all (explicit and implicit) user vectors are positive. On the other hand, we introduce new user vectors to the restricted master problem, user vectors with negative reduced costs, denoted by $\{U_l^*(S_k)\}_{l=1}^L$. If $\Omega_l^*[\Lambda(S)] \geq 0$ for a particular l , we will simply leave out bucket plan l in $\{U_l^*(S_k)\}_{l=1}^L$.

Figure 4 shows the flow of our column generation procedure to solve LP-BPO, with

index k represents the progress of the iterative algorithm:

A NUMERICAL ILLUSTRATION FOR BUCKET POOLING

We illustrate the column generation technique applied to our bucket pooling optimization problem, with problem parameters depicted in Tables 4 and 5. In this example, there are seven different user types ($T = 7$) and four bucket plans ($L = 4$).

An initial set of user vectors is used as the starting columns in the restricted master problem: at least seven linearly independent column vectors. The dual solution of the restricted master will be used to generate “attractive” user vectors to construct an augmented master problem in the next iteration. We choose to solve four different subproblems, examining each of the four bucket plan types to see if a user vector can be generated with negative reduced cost. Table 6 shows the progress of our column generation procedure. We now narrate the progress of the iterative procedure.

The algorithm starts (iteration #0) with seven user (column) vectors and it generates optimal dual variables for the seven (primal) constraints (one for each of the user types). Each constraint corresponds to satisfying the number of users in each user type, that is, all users have to be assigned to some bucket plan. The restricted master (and its dual) is an LP relaxation of the integer problem. The optimal objective value is \$70,944. Using the optimal dual in each of the (plan type) subproblem, we generate two additional columns (user vectors), bringing the number of columns to nine with which a new restricted master (iteration #1) is solved. Subsequent iterations bring the total number of columns to 10, 11, 13, 15, ... and eventually to 21. At the 9th iteration, no new columns are generated in the subproblems (the optimal value of all subproblems are nonnegative), we declare an optimal solution for the original bucket pooling optimization problem, in its LP relaxation.

Table 7 shows all the columns vectors used in the iterations. Only 7 of the 21 columns will be active in the optimal LP solution of the master problem. Note that the initial set

of user vectors are linearly independent, otherwise, the initial restricted master problem may be infeasible.

Table 8 shows various statistics of the optimal solution of BPO-LP. As an example, user vector #17 consists of three users of type 2 and two users of type 6, with a total of five users. This user vector has an expected usage of 5750 min and a standard deviation of usage 720.56 min.

$$\begin{aligned}\mu^{j=17} &= \sum_{t=1}^T v_{tj} \mu_t \\ &= 3 \times 250 + 2 \times 2500 = 5750. \\ \sigma^{j=17} &= \sqrt{\sum_{t=1}^T v_{tj} \sigma_t^2} \\ &= \sqrt{3 \times 80^2 + 2 \times 500^2} = 720.56.\end{aligned}$$

The usage profile of this user vector $(\mu^{17}, \sigma^{17}) = (5750, 720.56)$, will be evaluated under bucket plan B, with plan parameters $(F_B, B_B, \delta_B) = (225, 6500, 0.25)$, using Equation (2). The cost of this user vector is calculated to be \$258.88, which includes an additional feature fee of \$20 (four additional users at \$5 each). In all, 15 such plans will be used costing $15 \times 258.88 = \$3883.15$ —the cost to serve 15 bucket plans of type B for user vector #17. Note that in the LP solution some of the bucket plans are fractional. For example, user vector #18 will be in the optimal solution using bucket plan B, 4.65 times.

Table 8 also shows the round-up (from the fractional LP solution) and a round-down solution. The round-up solution will be feasible, but it will serve more than the required users. For examples, a total of 205 users of type 1 will be included in the round-up solution while only 200 are required; for user type 2, fifteen (slack) more users are included in the round-up solution; five more for user type 3 and one more for user type 7. The LP solution has an optimal objective value of \$53,062, which is a lower bound of the optimal integer problem—but it is not feasible. The round-up solution has a value of \$53,962, which is \$630 over the lower bound of the LP solution, or no more than 1.19% over the

Table 9. Bucket Pooling: Round-Down LP Solution Deficit

		# Users Served	Additional Need
1	200	187	13
2	150	141	9
3	120	108	12
4	100	100	0
5	150	150	0
6	230	230	0
7	50	48	2

optimal integer solution. The last row of this table shows the z -value of each user vector: how many standard deviations (of minute usage) is the minute allowance above the mean usage. For example, we again examine user vector #17, subscribed to bucket plan B.

$$z_{17} = \frac{(B_B - \mu_{17})}{\sigma_{17}} = 1.0409. \quad (11)$$

We can view the z -value as a “cushion” for each user vector–bucket type combination, showing the margin (measured in the unit of standard deviation) that the bucket allowance is providing, above and beyond the expected usage (of the user vector). This cushion ranges from 0.92 to 1.28. The cushion is used to avoid overage charge, which costs \$0.25/min.

The round-down solution is not feasible where 36 users are not provided for Table 9 shows the deficiency: 13 type 1 users, 9 type 2, 12 type 3, and 2 type 7 users still need to be provided for. However, one can augment the round-down solution to provide a feasible integer solution.

We can then solve the much smaller residual problem: find the best user vectors and their respective least cost bucket plans to provide service to these 36 users.

Table 10 shows the details to augment the round-down solution so that the neglected 36 users will be covered, in the Round-Down⁺ row. Three more user vectors are generated. The resultant cost of the augmented round-down solution equals \$53,148, which is only 0.16% above the LP optimal solution—a slight, but nontrivial improvement over the round-up solution (where there

were slacks: serving more users than what is demanded).

We now present a case study to illustrate the benefit of total pooling.

TOTAL POOLING CASE STUDY

This case study involves 15,619 users with actual usage history, varying from six months to well over two years of usage data for each user. Figure 3 is a scattered plot showing the diversity of these user profiles (μ_j, σ_j).

Table 11 contains some statistics about these users. The largest monthly (average) usage is about 3750 min, while the smallest average user consumes 20 min/month, with the overall mean usage of 458.53 min/user. The variation of usage (in terms of the standard deviation of usage) range from a maximum of 2126–6.16 min. We also provide statistics of coefficient of variation of each user, defined as the ratio of σ over μ , which ranges from 0.03 to 2.45.

There are six plans available for this group of users, detailed in Table 12. This table also shows the result of our right-sizing operation using Equation (2), which finds the least average cost plan individually for each of

the 15,619 users. Many users are assigned the smallest plan, while two large users subscribe to Plan 6. Before right-sizing, most users subscribed to Plan 3 (the default plan), while large users pick larger plans.

The pre right-sizing monthly cost averaged about \$1,100,000. Right sizing alone reduces monthly cost by 17% to \$938,971. Typical savings from right-sizing range from 15% to over 25%. Note that the figure of \$938,971 is not the actual monthly cost. Rather, it is computed using Equation (2) as an average cost for each user using individually optimized plan.

Total pooling incurs an additional per user feature fee of \$4 (\$5 list price with a negotiated 20% feature fee discount, which is typical). This feature fee alone adds more than \$60,000 to this pool of users. The mean and standard deviation of pooled usage is computed to be:

$$(\mu_M, \sigma_M) = \left(\sum_{i=1}^N \mu_i, \sqrt{\sum_{i=1}^N \sigma_i^2} \right) \\ = (7,161,846, 33,588).$$

The following optimization problem will be solved to find the optimal number of plans (of each plan type), $\{n_k\}_{k=1}^K$, for this user pool, using Equation (4). Note that we have used the weighted average of all the overage rates (weighted by the number of plans of each type in the optimal pool) to represent the overage rate for the pool. It turns out the optimal plan selection is not sensitive to the

pool overage rate.

$$C_{TP}^* \equiv Nf + \min_{\{n_k\}_{k=1}^K} C \left[(\mu_M, \sigma_M); (F^P, B^P, \delta^P) \right], \text{ with } (F^P, B^P, \sigma^P) \\ \equiv \left(\sum_{k=1}^K n_k F_k, \sum_{k=1}^K n_k B_k, \frac{1}{N} \sum_{k=1}^K n_k \delta_k \right).$$

The resultant pooled solution is shown in Table 13, where only the largest and the smallest plans are active in the optimal solution.

Table 14 shows relevant cost savings statistics for this case study. Note that each user is charged a feature fee of \$4 a month for the pooling privilege.

The savings from right sizing comes from two factors. The first factor is the misalignment of incentives when a sales representative recommends subscription plans to the users with his income being dependent on commission. Many small users subscribed to Plan 3, which is the default plan for this company. Many new users are “advised” to choose a “large enough” plan, just to be safe. Once the plan assignment is made, there is no review process to adjust—which is the second factor. A typical application of total pooling (from pre-optimization) usually results in percentage savings ranging between 20 and 30%.

CONCLUDING REMARKS

Mobile communication has become a necessity in today’s corporate world. This article examines the minimization of mobile voice expenses, starting with individually optimized plan for each user to rather complex plan sharing configurations. The challenge is to determine what is to be optimized since voice (minute) usage usually varies from one month to the next. A casual corporate mobile phone user typically subscribes to a plan recommended by a sales representative motivated by commission, which is not incentive compatible. Right-sizing an individual plan serves two purposes. First, it prescribes

the least cost plan (over the long run) should an individual stay on a stand-alone plan. Secondly, right-sizing provides a benchmark against which the benefit of pooling can be quantitatively measured.

Total pooling is relatively straightforward as all users share a common pool of minutes. The usage profile of the pool (in terms of the average total pooled usage and its standard deviation) can be readily determined. The optimization is to choose the right mix of available plans so that the total (expected) pool cost can be determined.

We argue that chargeback of the total pool cost to each individual user should not be proportional to the actual usage of a user, as a user with more usage variation contributes to a more expensive plan mix configurations. The right-sizing solution provides a benchmark so that the savings (due to pooling) can be equitably distributed to the users. A case study (with more than 15,000 users) is presented to show the savings due to right-sizing and then to total pooling. Typical savings can range between 20 and 30%. In our case study, the saving is in the high 30%. Many Fortune 100 companies incur tens of millions in annual mobile communication expenses. Quantitative optimization can certainly contribute to attractive savings.

Bucket pooling assigns users to share in various bucket plans (each with its own plan parameters), whose complexity defies a solution. We reformulate the problem by clustering users into T types, each with a common usage profile (e.g., 1000 users into seven types). The resultant optimization becomes a cutting stock problem with many columns (cutting pattern, or usage vector in our environment), which will be generated as needed in a master–subproblem iteration. The master problem will generate dual variables, being passed to the subproblem. A subproblem will determine if a better column can be generated. Optimality is established if the subproblem fails to generate a better column. We provide a numerical example to show the column iteration procedure as well as a process to round (up or down) the fractional LP solution to a feasible (near) optimal integer solution, without fraction of 1% to the LP solution.

Many features are to be developed (perhaps not as mathematically interesting) to provide a complete expense management system for mobile communication services (voice and data). These features include: data plan optimization, continuous expense monitoring to detect exception, real-time alerts to inform users of less expensive alternatives (e.g., corporate conference bridge, overseas roaming), and corporate policy compliance (abuse of use). Operations research techniques can definitely be productively applied in the mobile communication expenses management space.

MANAGING PERISHABLE INVENTORY

OPHER BARON
Rotman School of Management,
University of Toronto, Toronto,
Ontario, Canada

INTRODUCTION

This article discusses inventory management of perishable items, including the differences between inventory models that consider items' perishability and the standard models that ignore this issue. We hope that this article will help fostering the interest of students and researchers in inventory control of perishable items, and ultimately help improving the inventory control of perishable items in practice.

To emphasize the importance of appropriately managing inventory of perishables, note that Ref. 1 estimates the total cost of unsalable merchandise of suppliers to drug-stores and supermarkets in 2005 by \$2.05 billion. This cost goes directly to the bottom line of many of these companies. Moreover, higher clock speed in many industries results in shorter and shorter life-cycles of many products. The inventory control of such products might become similar to the one of perishable items as well after some period, when a newer version is presented, the value of old items declines significantly. One important difference between items with short life-cycle and perishables is that in some cases, the firm controls the introduction of the new technology. Still, much of the insight derived for managing perishable inventory may be valid for products with short life cycles.

Most of the traditional inventory models analyzed in the literature (e.g., EOQ, (Q, r) , and (S, s) policies) assume an infinite shelf-life for items (see *Multiechelon Multiproduct Inventory Management*). (An exception

is the newsvendor model discussed in the section titled "Extending the Newsvendor Model".) Thus, when the shelf-life of the items stored is finite, traditional control policies may not be sufficient. For this reason, special purpose models that focus on the management of inventory of perishable items were developed. Our purpose is to highlight the reasons for these differences and enable further investigation of the models developed for perishable items by providing relevant references. A more technical discussion of the techniques employed in the analysis of perishable items is given in the article titled *Mathematical Models for Perishable Inventory Control* in this encyclopedia.

This article continues as follows: the section titled "Modeling Inventory Problems for Perishable Items" highlights the differences between inventory models for perishables and models that ignore perishability. The section titled "Taxonomy of Inventory Models for Perishable Items with Infinite Horizon" provides a taxonomy of models for controlling inventory of perishables based on Ref. 2, and lists some of the basic results of such models. An important observation from this section is that effective heuristics are required for the management of perishable items. Thus, the section titled "Developing a Heuristic Control Policy" demonstrates the development of such a heuristic based on Ref. 3, and finally, the section titled "Future Research Directions" lists probable directions for future research on the management of perishable items.

MODELING INVENTORY PROBLEMS FOR PERISHABLE ITEMS

The analysis of inventory systems is primarily focused on the tactical question of which inventory control policies to use and the operational questions of when and how much inventory to order. By and large, these are the main questions for managing the inventory of perishable items as well. This section reminds the reader of the assumptions used

in modeling standard inventory systems for nonperished items and then lists the special features of models for perishables. It concludes by generalizing the newsvendor model to consider items with finite shelf-life. In the process, we present relevant notation.

Inventory Modeling for Nonperishables

In inventory models for nonperishables, time is measured either in a discrete (i.e., periodic) or continuous fashion. The choice of time measurement is often related to the review period (periodic or continuous) and to the model horizon, T , that may be a single period, finite, or infinite horizon. The replenishment lead time, L , may be assumed to be zero, deterministic, or stochastic (with or without order crossings). The customers arrival rate per time period, λ , may be deterministic or stochastic, each individual's demand, D , may be deterministic or stochastic, and D may be discrete or continuous. A typical assumption is that the arrival process is Poisson with rate λ ; $D = 1$ (see *Poisson Process and its Generalizations*). Finally, when there are no items on the shelf, that is there are shortages, demand is typically assumed to be backlogged or lost.

The costs considered in the management of standard inventory systems are per unit procurement cost, c ; per unit selling price, p ; order setup cost, $K \geq 0$; and holding cost per unit per time period, $h > 0$. Another cost is that of shortages. The shortage costs can include a one-time cost per shortage, $K_b \geq 0$ if shortages are backlogged, or $K_l \geq 0$ when shortages result in lost sales, and a cost per unit per unit time, $c_b \geq 0$, in cases of backlog, or a cost per unit, $c_l \geq 0$, in the case of lost sales.

Special Features of Models of Perishables

In addition to the above list of characteristics, modeling of inventory for perishable items also requires a characterization of the time to perishability, L_p . This time to perishability may be either deterministic or stochastic. Moreover, when orders arrive in batches, all items in a batch may share the same time to perishability, or each item may have its own shelf-life. An alternative assumption is that

the inventory of good items is deteriorating with time at some rate, as in Ref. 4.

The two most common models for perishability are outdatedness due to reaching expiry date (e.g., food items or medicine) and sudden perishability due to disaster (e.g., spoilage because of extreme weather conditions). The perishability due to outdatedness is typically modeled as a deterministic time to perishability and the perishability due to disaster is typically modeled as an exponential (or its discrete counterpart, geometric) time to perishability. This is because the memory-less property of these distributions often results in more tractable models.

The treatment of lead time in the management of inventory for perishable items is also not trivial. One difficulty is that the items might perish during the delivery time. This might be addressed by assuming that the supplier supplies fresh items upon their delivery and changes their lead time accordingly. For example, when the lead time is deterministic and items' shelf-life is exponential, we can assume that delivered items are fresh by modeling the lead time as a geometric random variable.

In the example above, changing the lead time to support the assumption that supplied items are fresh complicates the model because it introduces another uncertainty in the model; namely, the corrected lead time becomes uncertain. To avoid complicating the model, much of the literature on perishable items assumes that supplied items (after the lead time) are fresh.

Another complication is that when lead times are long relative to the items' shelf-lives, there might be several orders out at the same time. Then, orders might cross each other. This potentially affects the shelf-life distribution of delivered items. (Order crossing typically increases the complexity of traditional models as well.)

A general difficulty caused by the presence of lead time in a stochastic environment is that shelf-life of items in stock depends on which batch they arrived at. Thus, the controller should keep track not only of the quantity of the items on shelf but also the length of time different items are on the shelf; that is, their age and its distribution.

Another challenge in the analysis of perishable items is that items that have not yet perished may have different remaining shelf-life. (Either because items have a unique shelf-life, or because batches with common shelf-lives arrived in different periods.) Thus, the information required to completely characterize the on-hand and on-order inventory includes not only the quantity of inventory but also the remaining shelf-lives of each unit in the inventory. This increase in information requirement makes the analysis of multiechelon supply chains for perishable products especially challenging (because even for standard items, such an analysis often relies on dynamic programming and suffers from the curse of dimensionality). Therefore, some important theoretical contributions developed in the analysis of perishable items address the information required to characterize the inventory level process. (See the discussion in the section titled “Models Without Order Setup Cost or Lead Times” and in the article titled **Mathematical Models for Perishable Inventory Control** in this encyclopedia).

Another relevant decision in managing perishables when items of several different ages coexist, is items dispatching to fulfill orders. In such cases, it might not be optimal to dispatch products in a first-in-first-out fashion. For an extreme case, consider the following example.

Example 1. A last-in-first-out dispatching policy would decrease the effect of perishability when an item’s shelf-life follows a new worse-than-used distribution. (Let $F_{L_p}(s)$ denote the cumulative distribution function of the shelf-life. Then, if

$$1 - F_{L_p}(s + t) \geq (1 - F_{L_p}(s))(1 - F_{L_p}(t)) \\ \forall s \geq 0, \forall t \geq 0,$$

we say that L_p has a new worse-than-used distribution.)

While perishable items with a new worse-than-used shelf-life are hard to find in practice, this example highlights the difficulty of characterizing the optimal dispatching policy. To substantially complicate the exact

analysis of the optimal control policy for perishables, it is enough that a newly arriving batch may have a shorter shelf-life than that of existing items. Moreover, in cases when customers may control the items’ dispatching they may prefer fresher items (consider items such as milk), causing the actual dispatching to differ from first-in-first-out.

Extending the Newsvendor Model

The newsvendor model discussed in the article titled **Newsvendor Models** in this encyclopedia is an exception in the standard inventory literature, because it considers perishability. This model considers the order quantity required to maximize the profit over a single period when the demand over the period is uncertain. In addition to the costs listed above, the newsvendor model also considers the salvage cost of perishable items c_s , which can be negative or positive.

The newsvendor model can also be used to model perishable items that can be ordered only once. Now, we model the length of the single period (i.e., the lifetime) as uncertain, but there are no further procurement opportunities. In this case, the uncertainty in the demand depends on both, the uncertain demand per time period and the uncertain length of the selling season. A similar idea was first investigated in Ref. 5, which in contrast to the newsvendor model, allows several ordering opportunities before the perishability time.

To express the uncertainty in demand in these settings, we assume that the shelf-life L_p is a discrete random variable with a z -transform $Z_{L_p}(z) = \sum_{i=0}^{\infty} z^i \Pr(L_p = i)$ and that the demand in time period i is independent and identically distributed, D_i , with a probability density function (pdf), $f_{D_i}(x)$, and a moment-generating function, $L_{D_i}^*(\alpha) = \int_{-\infty}^{\infty} e^{\alpha x} f_{D_i}(x) dx$. Then, the horizon considered by the planner is $T = L_p$, the overall demand during the period, D_T , is a random sum of random variables with a moment-generating function $L_{D_T}^*$:

$$L_{D_T}^*(\alpha) = E(L_{D_i}^*(\alpha)^{L_p}) = Z_{L_p}(L_{D_i}^*(\alpha)).$$

Example 2. If $L_p \sim \text{Poisson}(p)$ and $D_i \sim \text{Normal}(\mu, \sigma^2)$ and are i.i.d, Then $Z_{L_p}(z) = e^{p(z-1)}$, $L_{D_i}^*(\alpha) = e^{(\mu\alpha + (\sigma\alpha)^2/2)}$ and the moment-generating function of overall demand over the period is

$$L_{D_T}^*(\alpha) = e^{p(\exp(\mu\alpha + (\sigma\alpha)^2/2) - 1)}.$$

Because the moment-generating function fully characterizes the demand distribution over the products' random shelf-life, the standard solution of the newsvendor model can be implemented to maximize the profit even when the valuable shelf-life of the items is uncertain.

TAXONOMY OF INVENTORY MODELS FOR PERISHABLE ITEMS WITH INFINITE HORIZON

As shown above, the newsvendor model is useful in the inventory management of perishable items that can only be ordered once. However, many perishable items such as food and medicines are consumed over a much longer horizon; then a single order is not practical. Finite horizon models were addressed in the literature almost solely in the discrete review settings. In contrast, infinite horizon models were considered in both discrete and continuous review settings. Below, we describe the primary models, assumptions, and results in the inventory literature on perishable items. We follow the classification of Ref. 2 in the section titled "Taxonomy of Inventory Models for Perishable Items with Infinite Horizon" because it is both thorough and recent. The interested reader is encouraged to read Ref. 2.

The infinite horizon models for perishables include a cost, c_p , per perished item. This cost replaces the salvage value of perished items in the newsvendor model. It is also possible to include a fixed cost, K_p , in cases where batches of items perish; however, most of the models do not include the latter cost.

A more detailed discussion of the state-of-the-art results for each of these models is given in the article titled *Mathematical*

Models for Perishable Inventory Control in this encyclopedia.

Discrete Review Systems

Models with No Fixed Order Setup Cost and No Lead Time. The simplest model is one in which items' shelf-life equals the review period. Then, different periods are independent and the standard newsvendor solution is optimal in each period. The second simplest model, in which items' shelf-life equals two review periods, is already much more interesting. This model was pioneered in Ref. 6, where it was shown that the optimal control policy is state dependent.

That the optimal control policy is state dependent, is somewhat surprising, because the optimality of the base stock control policy is easily established in discrete review models for nonperishables without order setup cost. Moreover, this result is also important because it implies that for models in this category, the simple base stock-level control is not optimal, in sharp contrast to the optimality of this control for nonperishables.

Thus, for perishable items, the optimal inventory control requires solving a dynamic programming problem. The difficulty in finding and implementing the optimal state-dependent controls motivated researchers to search for effective heuristics. For example, Broadheim *et al.* [7] suggested a heuristic that is based only on the age of the newest item in the system and the simulation-based study in Ref. 8 considered several heuristics including one that keeps the total number of items in the system fixed, ignoring their ages.

Models with Fixed Ordering Cost but no Lead Time. The research on this category was pioneered in Ref. 9, which highlights the complexity of the optimal control structure for these models and suggests heuristic for control of the system based on the (S, s) model.

A nice observation for this model of the Poisson demand with backlogs case is that the optimal reorder level is always at or below -1 . This result, which was established in Ref. 10, echoes the one in Ref. 11 for the continuous review system. The proof follows

because—with no lead time—higher reorder points would increase holding cost without reducing the backlog. (This result also holds in the case where customer's arrival process is Poisson and each customer requests some integer quantity of the product.)

Models with Lead Time. The inclusion of positive lead time leads to much more complicated models, as the number of states required for the dynamic program increases. With lead time, one needs to also keep track of the age of ordered items. This model is considered in Ref. 12, where methods to solve it are suggested. Recently, Berk [13] analyzed the (Q, r) periodic review inventory model for perishables with lead time by using the effective shelf-life distribution and assuming lost sales.

Discussion. The assumption of zero lead time in the case of a discrete review system is often justified if the lead time is shorter than the review period. Therefore, the analysis of such models (with periodic review and no lead time) is valuable. The zero lead time assumption is not as meaningful for continuous review models or when the lead time is long and makes reviewing the items at such intervals too expensive.

From an analysis point of view, treating perishable items requires consideration of the age distribution of the on-hand inventory in both ordering and dispatching of perishable items. Dispatching is also important because, typically (and in contrast to Example 1), the value of older items in stock is lower than that of the newer ones. The challenges in both ordering and dispatching of perishables causes the traditional optimal policies for nonperishable items to be suboptimal for perishables.

It turns out that the optimal control policies for perishable items are fairly hard to characterize. This difficulty encouraged researchers to develop effective heuristics for the periodic control of perishable items in the absence of lead time. However, no such heuristics were developed for models with long lead time (Williams and Patuwo [12] give an exact analysis of several relevant cases and suggest guidelines for developing such heuristics).

Continuous Review Systems

Models without Order Setup Cost or Lead Times. This category was motivated to model blood banks. It was originated by Graves [14], who assumed that the items are continuously produced, perish after a deterministic time, and that demand follows a compound Poisson process with either a single unit or an exponential demand at each arrival. A large body of work within this category was done by Perry *et al.* in Ref. 15 and references therein; thus Karasesman *et al.* [2] named it the *Perry model*.

An interesting observation that is used in the analysis of the Perry model is that its performance can often be characterized based on knowledge of the virtual death process, that is, the time until the next perishability [16].

The main assumption made in many of the models within this category is that good items arrive one by one independently of the decision making. Thus, in contrast to standard inventory models, the controller does not decide on when and how much to order. Still, the controller might affect the arrival rate of good items by advertising, for example.

Because of this lack of control on the input, most work on the Perry model focused on performance analysis rather than on finding optimal controls.

Models without Order Setup Cost but with Positive Lead Time. The first work on continuous review models without setup cost but with lead time is given in Ref. 17 where, as in many subsequent works, the performance of an $(S - 1, S)$ control policy is investigated. However the optimality of this control policy is not established, even when time to perishability and interarrival times are exponential. In fact, in view of the fact that base stock is not the optimal policy in the corresponding discrete review model, even in the absence of lead time, this control policy is probably not optimal for the continuous review models either. While some study of problems with fixed lead time and time to perishability has been pursued [18], the theoretical results about these applicable models are far from being complete.

Models with Order Setup Cost. Models with order setup cost can be portioned into ones with a fixed or variable order size, corresponding to the (Q, R) or the (s, S) standard inventory models. Both types of models can be analyzed as cost minimization problems, possibly subject to some service level constraint.

For fixed batch size problems, two policies were considered: the standard (Q, R) and the (Q, R, T) policy, where orders of a batch are triggered by either the time passed (since the inventory level was Q) being T , or by the inventory level falling below R [19].

The vast majority of work allowing for variable order size assumes no lead time, as in Ref. 11. In Ref. 11, it is established that with Poisson demand the (S, s) is the optimal policy when shortages are either backlogged or result in lost sales, and also that $s < -1$ or $s = 0$ for these models, respectively. (The insight behind the proof on the optimal reorder point is similar to the one for the corresponding discrete review model discussed in the section titled “Models with Fixed Ordering Cost but no Lead Time.”)

Recently, Gurlur and Ozkaya [20] considered a zero lead time with backlog (s, S) policy for perishables. They used sums and integrations of relevant distribution functions to express the expected cost rate function for their model and developed a heuristic for the positive lead time case.

Discussion. To summarize, stochastic analysis is the main tool used in the investigation of continuous review models for perishable items. This analysis is not trivial and the characterization of the optimal control policies is more complicated than in the periodic review models. Therefore, there is a need to find effective control policies for these models as well, especially in the presence of lead time.

There is still a place for developing efficient heuristics for the control of continuous review policies for perishables with lead time. Both the heuristic reported in Ref. 20 and the one for the no lead time case from Ref. 3, which is also reproduced in the next section, seem good starting points for finding such heuristics.

DEVELOPING A HEURISTIC CONTROL POLICY

As discussed above, there is a need for developing effective control policies for both, continuous and discrete review models of perishable items. Below, we discuss such a heuristic based on Ref. 3. Consider a continuous review model with no lead time, where the customers arrival process is Poisson with rate λ and each customer requests a continuous random quantity D of items with a mean demand size of $E(D)$. The costs considered are the order setup cost, K , holding cost per item per time period, h , and cost of perishable items, c_p . Let us focus on an (S, s) control policy and allow no backlog, which is legitimate due to the zero lead time assumption. Thus, $s = 0$ is optimal and due to the Poisson arrival process, the times where the inventory level is raised to S are renewal epochs (see **Definition and Examples of Renewal Processes**, properties of renewal processes)

In the standard $(S, 0)$ model without perishable items, the end of the inventory cycle, denoted by T_S is caused only due to the arrival of a demand. Of course, T_S is a random variable that depends on S and on the demand arrival process. But when items are perishable, cycles can also end due to perishability, at time L_p , which is the random variable describing the time to perishability of a new batch. To emphasize that the model focuses on perishable items, we denote the time to end the cycle by $\tau = \min(T_S, L_p)$ and the corresponding control policy by (S, τ) , as in Ref. 3.

Figure 1 shows a sample path of inventory over more than two inventory cycles. The first cycle ends due to the demand, as in a standard $(S, 0)$ model; then $\tau = T_{S1} \leq L_{p1}$. The second cycle ends due to perishability; then $\tau = L_{p2} < T_{S2}$.

Let $V(t)$ denote the inventory level at time $t \in [0, \tau)$ from the beginning of the cycle. Thus, $\mathbf{V} = \{V(t) : t \geq 0\}$ is a regenerative process such that $V(0) = S$. We let $V(\tau)$ denote the inventory level at the end of the cycle and use E as the expected value operator (both $E(V)$ and $E(V(\tau))$ are well defined because $\mathbf{V}$ is a regenerative process). Then, the long-run

Figure 1. Sample path (S, τ) models.

average cost $C(S)$ is

$$C(S) = \frac{K + c_p E(V(\tau)I\{\tau < T_s\})}{E(\tau)} + h E(V), \quad (1)$$

where $I\{\cdot\}$ is the indicator function with a value 1, if the event $\{\cdot\}$ occurs and 0 otherwise.

To find a heuristic control policy, we replace the stochastic demand assumption with a deterministic demand with a rate $\lambda E(D)$. Then, starting at the reorder level S for any time t before the end of the cycle, we have

$$V(t) = S - t \lambda E(D) \quad t \in [0, \tau].$$

Therefore, if items do not perish within a cycle its length is $T_s = S/(\lambda E(D))$. Letting $f_{L_p}(t)$ denote the pdf of L_p , the expected cycle length is given by

$$\begin{aligned} E(\tau) &= E(\min\{L_p, T_s\}) \\ &= \int_0^{S/(\lambda E(D))} t f_{L_p}(t) dt \\ &\quad + \frac{S}{\lambda E(D)} \Pr\left(L_p > \frac{S}{\lambda E(D)}\right). \end{aligned} \quad (2)$$

Since for every $t < \tau$ we have $V(t) = S - t \lambda E(D)$ and, as in the EOQ model, the average inventory resulting from an inventory triangle of height Y is $Y/2$, we have

$$\begin{aligned} E(V) &= \int_0^{S/(\lambda E(D))} \left(S - t \lambda E(D) + \frac{t \lambda E(D)}{2}\right) \\ &\quad f_{L_p}(t) dt + \frac{S}{2} \Pr\left(L_p > \frac{S}{\lambda E(D)}\right) \end{aligned} \quad (3)$$

and

$$E(V(\tau)I\{\tau < T_s\}) = \int_0^{S/(\lambda E(D))} (S - t \lambda E(D)) f_{L_p}(t) dt. \quad (4)$$

Remark. This heuristic assumes a continuous and deterministic demand process, thus new demand arrives immediately after an old batch perishes. In practice, when there is no lead time, ordering the next batch after items perish can be postponed until the next customer's arrival. That is, the order at the end of the second cycle in Fig. 1 can be postponed until the first arrival in the third cycle. Such

postponement would increase $E(\tau)$ and can be incorporated into the heuristic by adding the expected time to an arrival to the expected cycle length whenever cycles end due to perishability. In contrast, when the demand size is continuous, it is likely that when the cycle ends due to demand there is some demand that should be satisfied from the next batch. Then when no backlog is allowed, a similar postponement is not feasible for cycles that end due to demand. In any case, postponing orders when cycles end due to perishability might not be beneficial when lead time is positive. Thus, in the example given below, we ignore such postponement and use $E(\tau)$ as given in Equation (2).

Example 3. The heuristic when $L_p \sim \exp(\xi)$: Assuming $L_p \sim \exp(\xi)$ using Equations (2)–(4), we get the approximated control problem:

$$\min_S C^h(S) = \frac{K + \pi \left(S - \frac{\lambda E(D) \left(1 - e^{-\xi \frac{S}{\lambda E(D)}} \right)}{\xi} \right)}{\frac{1 - e^{-\xi \frac{S}{\lambda E(D)}}}{\xi}} + h \left(S - \frac{\lambda E(D) \left(1 - e^{-\xi \frac{S}{\lambda E(D)}} \right)}{2\xi} \right), \quad (5)$$

while in general there is no closed form solution to problem (5), it is easily solved numerically.

This heuristic, of solving Equation (5) was investigated in Ref. 3, for cases in which the time to perishability is exponential or deterministic, arrivals follow a Poisson process, and customers' demand is either a unit or exponentially distributed. For these cases, Baron *et al.* [3] expressed the optimal order up to level, that is, the one that minimizes Equation (1) denoted by S^* , and compared it to the order up to the level based on solving Equation (5), S^H . For these cases, the cost error of the heuristic is relatively small

(around 2% on average). Thus, Baron *et al.* [3] suggested that this heuristic be used for cases where S^* cannot be found.

FUTURE RESEARCH DIRECTIONS

Below, we discuss several research directions and explain their importance. Many of these extensions have attracted significant research for standard items, but in our opinion, they are not addressed well enough for perishable items.

The most important research direction for managing inventory of perishables is to develop effective heuristics for inventory control of such items. Some heuristic control policies were developed earlier, such as by Nahmias [21], who discusses heuristics for the deterministic shelf-life case. However, developing effective heuristics for additional settings is still required. Such settings should include both continuous and periodic review systems and focus on cases with positive lead times. A closely related research direction is to provide theoretical guarantees on the performance of different heuristics, similar to the established efficiency of power of two policies for standard inventory items [22].

The standard assumption in the literature on continuously reviewed perishable items is that the planning horizon is infinite. Investigating the inventory control of perishables for finite horizons in such settings also deserves more research attention.

Four other issues that have garnered a lot of attention for standard inventory items are their management (i) in multiechelon settings, (ii) when aiming to coordinate the supply chain, (iii) for multiple items, and (iv) in the presence of competition (see **Business Process Outsourcing** multiechelon, multiple items and **Supply Chain Coordination**). An important feature in investigating these issues is internal transshipment. Many models addressing nonperishable items ignore internal shipments, because the cost of internal shipments might offset their benefit. However, because transshipments of perishable items may reduce the proportion of perished items, the value of internal transshipments for perishable items is higher

than for nonperishables. Thus, allowing internal transshipments is preferable in models that consider multiple sites.

Initial steps at investigating the above issues for supply chains of perishable items were taken (Section 4 in Ref. 2). For example, for the supply of blood in multiechelon settings (Ref. 23 and references within), consider both, a rotation (or recycling) policy and a retention one. In a rotation system at the end of each period (e.g., day) the supplier gathers all unsold (and not yet perished) items from the retailers and then supply them at the beginning of the next period; in a retention system, supplied items are left with the retailers until they are demanded or perished. However, the literature addressing issues (i)–(iv) for perishables typically considered fairly restrictive settings. Therefore, there is room for addressing these issues and developing effective management policies for managing the flow and allocation of perishable items in supply chains.

Note that to properly address these issues, investigation of the strategic planning of supply-chain networks is required for perishable items. Appropriate models for supply-chain networks require as input, the inventory control policy used and their performances (see *Supply Chain Coordination*). For example, locating warehouses and distribution centers should consider the costs implied by different supply-chain configurations. However, in the absence of efficient methods to manage the inventory within the supply chain and to estimate the implied inventory-related costs, designing the network of the supply chain might be of limited value.

Another model that is well established for standard items is joint manufacturing, storing, and allocation of products for different customer types. This is also relevant for perishable items. An example is the choice made at a central depot that serves several different retailers with different importance. Then, an allocation of items may need to consider performance measures as seen by the different customer types. Such measures of service levels could be on-stock availability of “fresh enough” items, fill rates, and so on. In fact, inventory control of perishable items

subject to service level constraints even for a single customer type has won little attention. Such constraints could be quite specific in defining appropriate service levels in relation to the residual life of items sold. Customers might not be satisfied with only a high on-shelf availability, but may also demand that available items are fresh enough. Moreover, in some cases different customer types prefer different levels of freshness that require different storage processes. For example, the shelf-life of tomatoes is longer if they are kept on the vine, refrigerated (that may also reduce their flavor), or turned into a tomato paste, tomato juice, or ketchup. Thus, it is likely that formulating problems with different customer types would be very application dependent. Still, in view of the importance of these applications, for example in the health-care industry, this is a topic deserving further research.

The above discussion of different service levels and storage requirements for perishable items raises another question; namely, the effective analysis of the logistics required for the delivery of perishable items. Logistics planning for perishable items involves capacity, storage, production, and transportation decisions as well as their effect on items’ shelf-life. For example, some fruits are delivered to North America in ships, with part of their ripening occurring during this long and often uncertain transportation window. Once ripened, such fruits are often stored at cold temperatures to increase their shelf-life. Thus, managing the logistics process required to bring valuable items to final customers is not simple, and deserves further attention. Again, such research is likely to be application dependent.

An important issue that is unique for perishable items is the dispatching policy which may be complex even for a single customer type. In addition to the complexity highlighted by Example 1, the dispatching policy can also affect the demand. For example, consumers of food items such as milk, often check the “best before” date of items on the shelf. Thus, demand for a specific item depends not only on its availability on the shelf and its age, but also on the age and shelf availability of items of different ages. That is, there

are substitutability effects among items that differ by age. In addition, in this setting, the controller can only affect rather than dictate the dispatching policy. This is a mirror problem to the models in the section titled “Models Without Order Setup Cost or Lead Times,” where the controller can only affect rather than dictate the arrival of new items. Again, initial works on this subject exist (Section 5.2 of Ref. 2), but there is still plenty of opportunity for research in more realistic settings.

As the last but not the least research direction, we list the following simplifying assumptions that are often made in works on perishable items. Most of the references above assume that (i) demand is known (in case of stochastic demand its distribution is known), (ii) there is no seasonality, (iii) demand is independent of pricing, shelf space allocation, and inventory level, (iv) order yield is perfect, and (v) there is no substitutability of items (both within items of different ages and among different products). For nonperishable items, all of these assumptions have been relaxed to some extent. However, the vast majority of papers on managing inventory of perishables make these assumptions. (Several initial attempts at relaxing some of these assumptions are referenced in Section 5 of Ref. 2.)

MANAGING PRODUCT INTRODUCTIONS AND TRANSITIONS

ÖZLEM BİLGİNER

Department of Management Science and
Engineering, Stanford University,
Stanford, California

INTRODUCTION

Reducing time-to-market is commonly advocated as a source of competitive advantage. As a result, companies introduce new products more frequently than ever. For example, lifecycles are under a year for most electronic products [1]. In the semiconductor industry, a new processor is introduced every 18–24 months [2]. By launching new products faster than competitors, firms can rapidly respond to customer feedback, establish new standards, improve brand recognition, quickly introduce technical innovations, and capture a bigger share of the market, resulting in higher profits. Therefore, fast-paced product launches potentially bring tremendous value to firms. However, these launches also pose enormous challenges:

Companies that expand their product and service varieties now face a new set of problems: accurate demand forecasts, controlling production and inventory costs, and providing high quality delivery performance. (...) [I]ncreasing product lines can also decrease the efficiency of manufacturing processes and distribution systems. [3]

The period of product transitions is often the most vulnerable time for a company. Studies show that approximately 60% of new products fail in the marketplace [4]. Moreover, many of those products that make it in the market face rough transitions. As a result, product transitions can be costly due to excessive research and development (R&D) investment, marketing, and advertising costs of the product launch. In addition, there are

operational challenges that must be managed effectively, the failure of which may be detrimental. In the worst case, mismanaged product transitions may even lead to a company failure (e.g., Osborne Computers [1]).

This article serves as an introduction to product introductions and transitions, and as a survey of the literature on this important phase in a product's lifecycle. We define *product introduction* as the process of introducing a product, without considering the interactions with previous and future generations. *Product transition*, on the other hand, covers the introduction of the new product *and* the displacement of the previous generation [1]. In the next section, we provide a brief background of product introductions and transitions, and discuss supply and demand factors that need to be considered for a successful product launch. The dynamics of product launches depend heavily on how demand is generated. Of the various theories which explain demand generation, new product diffusion theory is among the most commonly used; this is discussed in the section titled "Diffusion Models." We then review the literature on product introductions in the following section and on product transitions in the section titled "Diffusion Models for Product Transitions." We conclude with potential research directions in the last section.

There is extensive literature on product feature selection and product line design, as well as on the product development structure of a company. Our scope in this article does not include these topics. Similarly, a stream of research in operations management literature considers pricing at the *end* of the product lifecycle; we do not consider the pricing of the old product unless it is in conjunction with the new product; hence, we omit a review of this stream as well.

PRODUCT INTRODUCTIONS AND TRANSITIONS

Launching new products frequently results in more product transitions (rollovers), and thus, situations where companies have to manage multiple product generations

simultaneously. Billington *et al.* [1] classify product rollover strategies as either *solo-product rolls* or *dual-product rolls*. In the solo-product roll strategy (Fig. 1a), at any given point of time, only one product is marketed; that is, the company aims to clear all of the old product inventory before introducing the new product. This strategy is simpler than the dual-product roll from the viewpoint of the company; however, planning has to be more precise because the old product has to sell out exactly at the time of the introduction of the new product in order to prevent a gap or an overlap. In the dual-product roll strategy (Fig. 1b), on the other hand, the old and new products overlap in the market for a period of time. As such, timing of the introduction is less of an issue; yet, products interact during the transition phase and managing this interaction can be challenging due to issues such as capacity management and cannibalization between products.

There are many supply and demand factors that companies should consider during product launches. We discuss several of these factors below:

- *Demand Forecasts.* Marketing indicators may have errors, especially at the time of a product launch. Companies may prepare themselves for a lower or a higher forecast than the original demand. As a result of poor sales forecasts, product launches may suffer from inadequate capacity decisions.

For example, after months of supply problems, Nintendo decided to increase the production of their popular console, Wii, by increasing production in one of their plants [5]. At the opposite end of the spectrum, the introduction of the Segway scooter suffered from overly optimistic sales forecasts. The Segway, which was released as a product that would revolutionize transportation, sold fewer than ten thousand units in the 2 years after its introduction. This was far short of the anticipated demand of 50,000 to 100,000 units [6], and the Segway failed to recoup its R&D expenses.

- *Pricing.* Pricing has a major impact on product launches. Eight months after the release of Intel's Pentium 4 processor, sales of the new product had not met expectations, in part, due to cannibalization by the Pentium III processor, which had a better value-price combination for consumers [2]. Product launches can be managed using price as a control mechanism by understanding the underlying dynamics of demand generation and by taking advantage of consumer heterogeneity. Proper pricing of a new product is a difficult balancing act. Higher prices will target only a minority of consumers (for whom the perceived value is higher than the price), may lead to slower adoption of the new product, and may result in excess inventory and capacity. Lower

Figure 1. Product rollover strategies: (a) solo-product roll strategy and (b) dual-product roll strategy.

prices will increase the potential market and may lead to faster adoption, but may increase the possibility of running out of stock due to accelerated sales. The initial price of a new product also affects the price trajectory of the product over its lifecycle. During transitions, the price of a new product impacts the demand of both the new and existing products. Therefore, pricing the products correctly enables a company to control the sales of (and hence the revenue from) the products not only during product launches but also over the lifecycles of existing and future product generations.

- *Timing.* The introductory timing of a new product should be carefully chosen. If the new product is introduced later, a longer R&D cycle may result in a better product. However, the company may suffer due to late entry and lose market share to its competitors (e.g., the qualification process in the semiconductor industry that we describe in more detail in the section titled “Timing of New Product Introductions;” see our discussion on Ref. 7). On the other hand, if the product is introduced too early, the market is captured, but there may be technical risks due to product imperfections or a product which lacks desired attributes (e.g., the problems of Microsoft with its platform Windows Vista). Additional concerns should be considered: the time gap between generations should be optimized to balance the trade-offs between product cannibalization and the age of the product platform. An introduction done too soon may lead to excessive cannibalization of the old product, and an introduction done too late may cause customers to switch to other platforms, decreasing brand loyalty.
- *Capacity Decisions.* One critical decision prior to a new product launch is the production capacity decision. It is difficult to determine the optimal capacity to build at the time of a product launch due to supply and demand uncertainties. If the capacity is set too high, the firm will

have to pay for the idle capacity. If the capacity is set too low, establish a parallel structure with the previous sentence the capacity investment cost will be lower, but the firm will hold inventory to manage demand surges during the introduction (which increases the inventory holding cost) and/or will suffer backorders and lost sales (which may hamper the product’s acceptance in the market). These trade-offs should be considered when determining the optimal capacity to build. Capacity allocation among new and existing products further complicates the trade-offs in capacity decisions. Interactions between products (relative product capabilities, relative prices, relative demand, etc.) should also be carefully analyzed. In 1992, based on its initial forecasts, GM allocated half of the capacity of its Detroit-Hamtramck plant to the redesigned Seville, Cadillac, and Eldorado models and the remaining capacity to Buicks and Oldsmobiles. However, demand for Seville and Eldorados quickly exceeded supply, leading to the loss of thousands of potential customers. GM eventually allocated the whole plant to those two models, but by then “the damage had already been done” [8]. In this example, GM was able to reallocate capacity. However, capacity may not always be interchangeable, which limits the possibility of reallocation based on supply and demand dynamics.

In such a fast-moving environment, to stay competitive, companies are actively seeking new ways to make their supply chains more responsive. For example, companies may invest in better forecasting techniques (such as information sharing with supply chain partners (see *Information Sharing in Supply Chains*) or collaborative planning and forecasting) to increase their knowledge of the sources of uncertainty. Alternatively, companies may undertake various initiatives to shorten product development processes in order to be flexible in the face of uncertainty.

For example, clothing manufacturer Benetton employed the concept of postponement to be more responsive to market conditions, and Intel Corporation aims to stay one product generation ahead of its competitors to maintain industry leadership [2]. However, even with extensive planning, contingency strategies that enable adjustments to initial decisions may be necessary due to market dynamics and supply and demand uncertainties. Therefore, any strategy that addresses new product launches should include the ability to learn, as well as the ability to set transition decisions at the beginning (i.e., primary strategies) and to adjust these decisions later (i.e., contingency strategies). This will enable a firm to observe supply and demand signals, revise its understanding of the transitional markets based on these signals, update market knowledge accordingly, and thus react effectively to the dynamics and uncertainties of supply and demand.

Until this point, we have reviewed the problems concerning product launches and some current practices of facilitating these launches in industry. In the following sections, we will review the related academic literature. We will start with demand generation models, specifically diffusion models, as a basic demand forecasting tool (see the section titled “Forecasting Techniques” in this encyclopedia). We will then review pricing and timing decisions in new product introductions and transitions. For new product introductions, we will also provide a brief review on supply restrictions and capacity selection. To the best of our knowledge, there are no equivalent studies of new product transitions.

DIFFUSION MODELS

One of the basic models that govern demand generation is diffusion. Rogers defines the diffusion of an innovation as “the process by which an innovation is communicated among the members of a social system” [9]. Thus, diffusion models focus on “communication channels, which are the means by which information about an innovation is transmitted to or within the social system” [10]. There are several diffusion models used in the literature; we provide a brief introduction to

the Bass model [11], which is one of the most widely used models in marketing.

The Bass diffusion model is a simple “epidemic” model, which represents the probability of a purchase at t given that no purchase has yet been made as a linear function of previous purchases [11]. To express the model mathematically, let $f(t)$ be the likelihood of adoption at time t , $F(t)$ the cumulative fraction of adopters at time t , p the coefficient of innovation, and q the coefficient of imitation. Then, the likelihood of purchase at time t given that no purchase has yet been made can be expressed as

$$\frac{f(t)}{1 - F(t)} = p + qF(t), \quad (1)$$

where $f(t) = dF(t)/dt$. The Bass model assumes that potential adopters of an innovation consist of two groups: the first term on the right-hand side of Equation (1) captures *innovators* and the second term captures *imitators*. Innovators are influenced *externally*, that is, by mass-media communication, and their purchases are independent of the previous purchasers (i.e., the first term is independent of $F(t)$) while imitators are influenced *internally*, that is, by word-of-mouth through previous purchasers (i.e., the second term is a function of $F(t)$).

Defining m as the market potential, $S(t) := mF(t)$ as the cumulative sales at time t , and $s(t) := dS(t)/dt = mf(t)$ as the instantaneous sales at time t , we can express the Bass equation in terms of sales as follows:

$$\begin{aligned} \frac{s(t)}{m - S(t)} &= p + \frac{q}{m}S(t) \Rightarrow \\ s(t) &= \left[p + \frac{q}{m}S(t) \right] (m - S(t)). \end{aligned} \quad (2)$$

Equation (2) is a differential equation that can be solved to provide $S(t)$ in closed form. Figure 2 displays the adoption of a new product as per the Bass model. Note that the Bass diffusion model assumes “first-purchase,” that is, there are no repeat buyers and purchase volume per buyer is one unit. Furthermore, the model assumes that the market potential m and diffusion coefficients p and q are constant over time, and that the adoption does not depend

Figure 2. Bass new product diffusion model: (a) instantaneous sales and (b) cumulative sales. [Source: Ref. 10]

on any marketing-mix variables like price and advertisement. The formulation in Equations (1) and (2) is for a single product lifecycle with infinite product availability and considers neither the phenomenon of diffusion in overlapping product lifecycles nor the concept of supply constraints.

Due to the limitations mentioned above, the Bass model can provide limited normative guidance. However, the Bass model and its various extensions have proven to be quite robust in practice. According to Bass, “the most important use of the model for forecasting purposes is the forecast made prior to product launch when there are no sales data upon which to base the forecast” [12]. The estimates of the Bass model parameters for different products and services have been developed using large databases for different industries. These estimates enable analysis of empirical studies using the Bass model; see Table 1 for a sample based on the work of Lilien *et al.* [13]. Lilien *et al.* report a low innovation coefficient $p = 0.000$ and a high imitation coefficient $q = 0.534$ for ultrasound imaging, which means that this product was slow to penetrate the market at first, but as the word-of-mouth effect increased, market penetration sped up. On the other hand, camcorders have a relatively higher $p = 0.044$ and a relatively lower $q = 0.304$; they penetrated the market fast and then over time the penetration slowed down. Actually, ultrasound imaging devices penetrated to only 20% of the market in the first 10 years after their introduction, while camcorders penetrated to 75%. In the next 10 years, both markets were almost fully penetrated.

MODELS FOR PRODUCT INTRODUCTIONS

In this section and the next, we provide a brief review of product introductions and product transitions in marketing and operations management literature. Our review is not comprehensive; instead, our goal is to provide a general understanding of this vast literature. In surveying the literature, we do not limit ourselves to diffusion models; in fact, some of the included models have general time-dependent demand functions.

Pricing of New Product Introductions

As mentioned earlier, one of the major drawbacks of the Bass model is its exclusion of price. To remedy this drawback, Robinson and Lakhani [14] modify Equation (2) as follows:

$$s(t) = \left[p + \frac{q}{m} S(t) \right] (m - S(t)) e^{-kPr(t)}, \quad (3)$$

where $Pr(t)$ is the price at time t and k is a price coefficient. According to Robinson and Lakhani, product price affects the likelihood of product adoption at any given time t but not the potential market size m . That is, only the adoption probability $f(t)$ is impacted by price. Using Equation (3), the authors study the optimal price sequence of a new product over the product's lifecycle. Their numerical results (obtained through simulation) indicate that, with a positive discount rate and experience-curve-based costs, cost-plus pricing performs poorly for a “rapidly evolving business.” The optimal price scheme should

Table 1. Sample p and q Values for Different Products

Product	Period of Analysis	p	q
<i>Electrical appliances</i>			
Blender	1949–1979	0.000	0.260
Can opener	1961–1979	0.050	0.126

Television, color	1965–1979	0.059	0.146

[Source: Ref. 13].

be dynamic and aggressive: the company should be ready to use penetration pricing (i.e., setting a relatively low initial price to penetrate the market, then increasing the price over time and decreasing it toward the end of the product lifecycle) and to potentially incur losses during the initial phases of the product launch. Robinson and Lakhani's work initiated a stream of research which aims to identify optimal price paths under different settings; we refer the interested reader to Section 4 of Ref. 15 for a brief review.

The impact of competition has also been analyzed in the pricing of new product introductions. Clarke and Dolan [16] study different pricing strategies in a duopoly. The authors compare myopic pricing (i.e., setting prices to maximize only the current period's profit), skimming pricing (i.e., setting relatively higher prices at the time of introduction and lowering them over time), and penetration pricing via simulation; they show that myopic pricing may yield highly suboptimal profits. Dockner and

Jorgensen [17] incorporate competition into the Bass model and analyze the optimal pricing strategies of competing firms where production costs decline with learning. In their model, the sales function depends on cumulative sales (as in the Bass model) and on prices of all competing firms. The authors also consider special cases of the demand function and determine the conditions under which the optimal price path is decreasing or increasing. Eliashberg and Steinberg [18] analyze competition between two firms with asymmetric cost structures and production modes. The first firm has a convex production cost and can hold inventory, whereas the second firm has a linear cost and cannot hold inventory. The firms compete on prices, production rates and, in the case of the first firm, inventory levels. The authors show that the first firm holds a positive amount of inventory at the beginning of the period, and stops holding inventory after a while. Prices first increase and then decrease.

Timing of New Product Introductions

In timing new product introductions, the main trade-off is between product quality, price, and time-to-market. Kalish and Lilien [19] are among the first to study this trade-off. The authors modify the Bass diffusion model to incorporate the effect of prices on market size as well as advertising-dependent diffusion parameters to determine the best time to enter a market. A premature entry results in a negative word-of-mouth effect due to a low quality product. On the other hand, being late to market results in lost sales. Kalish and Lilien do not provide general optimization results; instead, they provide a solution for a specific application where the objective is to maximize installed bases; that is, the number of current users of the products.

Bayus [20] focuses on the effects of competition on the timing problem and considers two scenarios. In the first scenario, the competitor is already in the market. Through numerical analysis, the author shows that it is optimal to accelerate product development and launch a low-quality product if the competitor's quality level is low, the time horizon is short, and product development costs are low. It is optimal to accelerate product development and launch a high quality product if sales are high and product development costs are low. In the second scenario, the competitor is also developing the product and the question is whether to be the first to market or not. The author numerically shows that it is optimal to accelerate product development and launch a high-quality product if the time horizon is long, sales are high, and product development costs are low. It is never optimal to be the first to the market with a low quality product in this case.

Recently, Özer and Uncu [7] have analyzed a similar problem. In their framework, a supplier decides when to finish design and launch his product to apply for a seller's product qualification. The problem has two stages. In the first stage, the supplier applies for a qualification. There are some trade-offs that the supplier faces. Entering early results in larger market share, higher production costs, and lower chances of getting qualified. Entering late results in lower market share, lower production cost, and higher

chances of getting qualified because waiting improves the manufacturing processes. If the supplier becomes *qualified*, then in the second stage, he determines the production quantities. Both, the qualification process and the demand are assumed to be uncertain. Even if the supplier decides to apply for qualification, he may not be qualified by the seller and, in turn, will not be able to "enter" the market. Using a dynamic programming approach (see articles in the section titled "Fundamentals" in this encyclopedia, for a review of the fundamentals of dynamic programming), the authors show that for the first stage, a threshold policy is optimal: the supplier decides to apply for qualification if his rank among the other suppliers is above some threshold. The authors also prove that, in the second stage, the optimal production policy is a state-dependent base-stock policy.

Supply Restrictions and Capacity Selection during New Product Introductions

Another drawback of the Bass model is that it does not model supply restrictions. Jain *et al.* [21] attempt to fill this gap by modifying Equation (2) as

$$\begin{aligned}\frac{dA(t)}{dt} &= \left(p + \frac{q_1}{m}A(t) + \frac{q_2}{m}N(t) \right) \\ &\quad (m - A(t) - N(t)) - c(t)A(t), \\ \frac{dN(t)}{dt} &= c(t)A(t),\end{aligned}$$

where $N(t)$ is the cumulative sales as in the Bass model, $A(t)$ is the number of waiting adopters, and $c(t)$ is the supply rate. The authors apply their model to data from the diffusion of new telephones in Israel, and find that the model is a good fit.

With similar models, Ho *et al.* [22] and Kumar and Swaminathan [23] study the supply-restricted diffusion problem to characterize the optimal time-to-market and capacity decisions of a firm. Ho *et al.* find that a myopic sales plan is optimal; that is, the firm should not delay demand fulfillment. The authors show that the firm may substitute capacity with inventory by delaying the product launch and building up inventory during that period. Kumar and Swaminathan, on the other hand, argue

that a myopic sales plan is not necessarily optimal. Via numerical analysis, the authors show that a build-up type heuristic, where the firm does not sell at the beginning but builds inventory instead, is optimal when unmet demand is lost and performs well when demand is backordered. It is surprising that these two papers derive such different results given that their models are quite similar. Kumar and Swaminathan argue that “although the models considered in Ho *et al.* (2002) and [our model] are different, it is unlikely that the differences in the models alone account for the contrasting results. Resolving this issue is the subject of future work.”

DIFFUSION MODELS FOR PRODUCT TRANSITIONS

The Bass model does not incorporate the interactions among existing products. Norton and Bass [24] relax the assumption of a single product and study successive generations of innovation using a cumulative sales growth model that accounts for cannibalization/substitution between two product generations. If $S_1(t)$ and $S_2(t)$ are the installed bases of the first- and second-generation products at time t , then

$$\begin{aligned} S_1(t) &= m_1 F_1(t) - m_1 F_1(t) F_2(t), \\ S_2(t) &= m_2 F_2(t) + m_1 F_1(t) F_2(t), \end{aligned}$$

where m_1 is the market size of the first-generation product (old product) and m_2 is the incremental market that exists only for the new product and cannot be satisfied by the old product. The fractions of adoption for each generation, $F_1(t)$ and $F_2(t)$, are given by the Bass model solution, and $F_2(t) = 0$ for all t before the introduction time of the second-generation product. The term $m_1 F_1(t) F_2(t)$ represents the cannibalization (or substitution) effect. The second-generation product will cannibalize the sales of the first-generation product and, over time, the installed base of the first-generation product will fall to zero. As such, this model formulation is more applicable to the repeat purchase of technology generations such as the transition from black-and-white to color

televisions, where all customers eventually move to the new product.

In the following sections, we review models that provide some normative guidance on pricing and timing issues during product transitions.

Pricing of New Product Transitions

The paper by Norton and Bass [24] does not account for marketing-mix variables such as prices. Padmanabhan and Bass [25] fill this gap by deriving the optimal pricing policy of a monopolist marketing successive generations of a product. Their model assumes that price affects sales at any instant but not the market size. The authors present various conditions when the optimal pricing of old and new generations would monotonically increase or decrease. They also present the optimal pricing policy when two generations are launched by independent producers. Padmanabhan and Bass’s results demonstrate that the integrated producer offers a lower price for the first-generation product than the independent producer and that both producers charge the same price for the second-generation product.

Lim and Tang [26] model product rollover strategies to determine the optimal entry time of the new product and the optimal pricing of the new and old products. The authors consider both solo- and dual-product rollover strategies, two-way cannibalization, and a linear price-demand relationship. As a consequence of this linearity, they are able to find the optimal decision variables in closed form, and they provide various insights on the dependency of optimal prices on parameters. They also determine the optimal time to introduce the new product and the optimal time to phase out the old product. Finally, the authors compare the two rollover strategies and provide conditions under which solo-product rollover is preferable to dual-product rollover.

Padmanabhan and Bass [25] and Lim and Tang [26] both assume that demand is known and that the firm does not hold any inventory. Li and Graves [27] relax these assumptions and study the optimal pricing decisions of two product generations under inventory considerations and uncertain demand. They restrict

the new product price to be constant and assume that the old product price can change dynamically. Due to the inherent complexities of changing prices dynamically, they propose a fixed-price policy and a heuristic to approximate that policy. The authors show that with excessive amounts of inventory, the performance of the heuristic approaches the optimal fixed-price policy.

Recently, Bilginer and Erhun [28] study the pricing problem where sales are represented as

$$\begin{aligned}s_1(t) &= m_1 f_1(t) - m_1 f_1(t) \gamma, \\ s_2(t) &= m_2 f_2(t) + m_1 f_1(t) \gamma.\end{aligned}$$

In the above equations, m_i is a price-dependent market size function for product generation $i = 1, 2$, $f_i(t)$ is the sales probability (this is a generalization of the Bass model $f(t)$), and γ is the price-dependent cannibalization coefficient. This coefficient is given by $\gamma = Be^{-\frac{Pr_2}{Pr_1}}$ where B is a number between 0 and 1 which represents the compatibility of the successive generations and Pr_i is the price of product generation $i = 1, 2$. The authors provide bounds on the optimal prices, and also propose two simple heuristics to find those prices. The first heuristic sets the prices ignoring cannibalization and the second one sets the old product's price assuming no cannibalization but optimizes the new product's price based on the old product's price. The authors show that both heuristics perform well. The second heuristic's maximum deviation from the optimal prices is only 4.75% and the average deviation is around 1% for the cases considered. Bilginer and Erhun further extend their model to the case where products are marketed by independent firms to analyze the effects of competition on prices. When there is no cannibalization, competition does not affect the prices. If cannibalization is price-independent, the old product's price increases under competition, while the new product's price may increase or decrease based on the parameters. If cannibalization is price-dependent, their numerical analysis shows that, in general, both prices fall with competition.

Timing of New Product Transitions

Determining the best time to introduce a new product to market is an important decision to make during product transitions. One of the earliest papers that model transition timing is Wilson and Norton [29]. In this paper, the authors study the optimal entry timing for a product line extension using a diffusion framework. In their model, the existing product has a higher revenue margin than the new product and the new product expands the market; nevertheless, the two products cannibalize each other. The authors show that, most of the time, it is optimal to either introduce the new product as early as possible or to not introduce it at all, depending on the demand parameters, market size, and relative product margin. They also show that in the remaining cases, it is optimal to introduce earlier rather than later. Mahajan and Muller [30] extend Wilson and Norton's model by allowing the marketing of more than two products at once and using general profit margins. Their results are very similar to Wilson and Norton's: it is optimal to either introduce a new product right away or wait until the old product matures. They apply their model to data obtained for IBM mainframes, and conclude that the time-to-market of two product families was too long.

Another stream of literature on new product launch timing treats the evolution of the current technology in the market as stochastic (e.g., the time between technology improvements and/or the amount of technology improvement may be unknown); see *Stochastic Dynamic Programming Models and Applications* for an introduction to stochastic models. Consider a firm that develops products based on available technologies and that must schedule its own product offerings based on its knowledge of a potential technology roadmap. Given the technology roadmap, the firm must determine when to replace its existing product and which technology to adopt. Balcer and Lippman [31] model the time between technology improvements as well as the amount of each improvement as stochastic. In order to adopt the latest technology, the firm needs to incur a fixed cost in addition to variable costs.

The firm's revenue is proportional to the technology level of the product. The authors show that a threshold policy is optimal; that is, it is optimal to adopt the latest technology if the technology gap (the difference between the latest technology in the market and the current technology of the product) exceeds a threshold. Paulson Gjerde *et al.* [32] extend Balcer and Lippman's model by assuming that the technology of the product is represented by a vector. The decision variables of the firm are the amount of innovation to invest in each of these dimensions. With a focus on when should firms make incremental versus frontier innovation, the authors characterize the conditions under which it is optimal to innovate to the level of the latest technology. Krankel *et al.* [33] extend these two models by assuming that the demand is diffusion type. (This paper also extends [29,30] by assuming a stochastic technology improvement process.) Using a dynamic programming formulation, the authors show that the optimal policy is a threshold policy, in which the threshold depends on the cumulative sales of the firm and the technological R&D level of the new product. Recently, Liu and Özer [34] have shown that under a faster technological pace, firms' expected total profits decrease unless their fixed costs are sufficiently low. Thus, the authors conclude that firms should try to lower their fixed costs of product development in order to stay profitable.

Several studies in the literature analyze the factors driving time between transitions. Souza *et al.* [35] study how factors such as "clockspeed" (the industry's speed of new product introductions), product development cost, production cost, inventory cost, and competition affect a firm's optimal new product introduction time and product quality decisions. They model this problem as an infinite-horizon Markov decision process (see the section titled "Introduction to MDPs" in this encyclopedia for an introduction to Markov decision processes) where the uncertainty derives from the product demand. Via an extensive numerical study and statistical analysis, the authors show that the optimal pace of new product introductions is mainly influenced by industry clockspeed. On the

other hand, the optimal product quality primarily depends on internal factors, such as the relative costs of introducing new products with incremental versus more substantial improvements. Similarly, Druehl *et al.* [36] analyze the factors that affect the time between product transitions. They assume that revenue margins decline exponentially over time and that the product development cost is U-shaped. The authors use the Norton and Bass [24] demand model, so the new product expands the market, but cannibalizes the old product's demand. Through extensive numerical analysis, Druehl *et al.* statistically show that the higher the diffusion rate, the higher the pace of product introductions. The authors also show that product development cost, market growth rate resulting from the new product, and the rate of margin decline highly impact the new product development pace.

CONCLUSION

Companies are under great pressure to serve their customers better, faster, and cheaper. This fast-paced environment requires agile and efficient supply chains that adapt well to changes in product characteristics and to an ever-changing market environment. Companies are launching new products more frequently and the pressures for success are greater than ever. In this article we reviewed the tools developed in industry and in academic literature to mitigate the problems encountered during the product introduction and transition phases of companies. We propose several directions for future research:

- With the exception of a few papers, the majority of the literature on new product introductions and transitions is focused on the organizational structure of the firm. There are many opportunities for the application of operations research and management techniques and tools. Inventory management, capacity planning and allocation during the new product introduction and transitions, and supply chain design for the new product are some of the unexplored areas of research.

- As we discussed in the first two sections, there are many supply and demand uncertainties burdening product launches. Surprisingly, almost all of the models in the literature ignore these uncertainties. There is a big opportunity to study these uncertainties systematically. The literature would also benefit from frameworks (similar to Refs 1 or 37) that combine many different supply and demand aspects of product launches to provide guidelines for successful product introductions and transitions.
- There is a need for better understanding of product transitions. Compared to the literature on product introductions, the literature on product transitions is still limited. For example, we were unable to identify any papers that analyze capacity allocation among multiple generations. Similarly, we did not encounter any work on using marketing-mix variables to alleviate capacity problems. Supply constraints in product transitions is also an open area. A better understanding of product diffusions and their extensions for product transitions would be valuable.
- A contractual partnership between tiers of a supply chain may alleviate some of the problems during the product introduction and transitions. To the best of our knowledge, the only paper that incorporates the interactions among multiple tiers of a supply chain into their framework is Li and Gao [38]. Li and Gao consider a periodic-review inventory system consisting of a manufacturer and a retailer, where the manufacturer introduces new products using a solo-roll strategy. The authors consider two cases, one with information sharing between the parties and one without, and devise the form of optimal contracts between the manufacturer and the retailer. They show that information sharing is beneficial for both parties when the inventory system is coordinated; however, this may not hold if the inventory system is not coordinated.

A deeper look at the contractual agreements and the interactions among supply chain partners during new product introductions and transitions is a potentially fruitful research direction.

- The Bass diffusion model easily becomes complicated when extensions are considered. This makes analysis quite tedious and many times, numerical solutions are the only viable outcomes. In this sense, future research should seek simple yet elegant ways to extend existing models in order to move forward and study the issues we have raised above. Practice calls for a better understanding of product transitions, especially under various demand and supply uncertainties. Demand generation models that enable such expansions would be especially welcome.

INTRODUCTION

Research and development (R&D) projects are inherently risky. Investors in R&D projects are often uncertain about the probability of eventual technical success, the costs and time needed to succeed, competitor activities, and market acceptance and financial rewards if a technical success occurs. Quantitative risk models can help to characterize and manage R&D risks and to answer such practical risk management decision questions as the following:

- *R&D Project Scheduling and Management.* How to order the activities within a project, decision rules for when to abandon a project.
- *R&D Project Selection.* Which projects to fund.
- *R&D Investment Strategy.* How intensely or quickly to pursue R&D.
- *R&D and Intellectual Property.* How to manage the results of R&D (e.g., through licensing and patent systems) to create incentives that will benefit society.

This article surveys methods for quantifying and managing R&D risks.

MINIMIZING R&D PROJECT RISKS BY OPTIMALLY ORDERING ACTIVITIES

A very simple model of an R&D project divides it into multiple activities, each having a known cost for attempting it and a known probability that it can be successfully completed if it is attempted. An R&D manager may wish to minimize the expected cost to either successfully complete the whole project or to learn (by trying activities and learning that they fail) that it cannot be completed. The problem of sequencing the project activities to achieve this goal can be solved easily in certain cases.

Example: Optimal Sequencing of Activities in a Risky Project.

Setting: Suppose that an R&D project can be completed successfully only by successfully completing both of two activities, A and B. The cost to attempt activity A is $c_A = 1$ cost unit; the cost to attempt B is $c_B = 2$ cost units; and the conditional probabilities of successfully completing these activities, if they are attempted, are $p_A = 0.8$ and $p_B = 0.5$, respectively. The two activities may be attempted in either order. The value of successfully completing the project (i.e., of successfully completing both A and B) is $V = 10$ benefit units (on a scale commensurable with the cost units).

Problem: (i) What investment strategy maximizes the expected value of investment in this set of R&D activities? (ii) What is the expected value of this R&D project?

Solution: (i) Attempting A first, and then B if A succeeds, yields an expected net value of

$$\begin{aligned} & (\text{cost to attempt A}) + (\text{probability A succeeds}) \\ & \times (\text{cost to attempt B after A succeeds} \\ & + \text{probability that B succeeds} \\ & \times \text{value obtained if B and A succeed}) \end{aligned}$$

$$\begin{aligned}
&= -c_A + p_A \times (-c_B + p_B V) \\
&= -1 + 0.8 \times (-2 + 0.5 \times 10) = 1.4 \text{ units.}
\end{aligned}$$

Symmetrically, attempting B first, and then A if B succeeds, yields an expected net value of

$$\begin{aligned}
&-c_B + p_B \times (-c_A + p_A V) \\
&= -2 + 0.5 \times (-1 + 0.8 \times 10) = 1.5 \text{ units.}
\end{aligned}$$

Since 1.5 is the higher value (and is positive), the optimal strategy is to attempt B before A, and the expected monetary value of the R&D project (if the optimal strategy is used) is 1.5.

More generally, trying A before B yields a higher expected value than trying B before A if and only if

$$\begin{aligned}
&-c_A + p_A(-c_B + p_B \times V) > -c_B \\
&+ p_B(-c_A + p_A V), \text{ or, equivalently, if} \\
&c_B(1 - p_A) > c_A(1 - p_B).
\end{aligned}$$

That is, for a project with positive expected value, *activities should be attempted in order of decreasing failure-probability-per-unit-cost ratio* (i.e., in order of decreasing $c_i/(1 - p_i)$, where $i = A$ or B in this example); this decision rule holds for any number of activities. (Projects with negative expected value should not be attempted at all, if the goal is to maximize expected value.)

The preceding example is especially simple because completing the project required all of the activities in it to be completed. The only decision was the order in which to attempt them. More generally, there may be several alternative ways to successfully complete an R&D project. A subset of activities is called a *path set* if completing all of the activities in it suffices to successfully complete the project. A *minimal path set* is one in which no proper subset of activities is a path set. The project succeeds if and only if all of the activities in at least one minimal path set are successfully completed. If minimal path sets are disjoint, then an optimal (expected value-maximizing) investment strategy is

to attempt alternative minimal path sets in decreasing order of success-probability-per-unit-expected cost (where the success probability for a minimal path set is the product of the success probabilities of the activities in it and the expected cost of the minimal path set is calculated assuming that activities *within* each minimal path set are sequenced in decreasing order of failure-probability-per-unit-cost ratio, as in the preceding example). Investment in a project should cease as soon as no minimal path sets with positive expected value remain.

These ideas can be extended to projects in which activities cannot be attempted in any arbitrary order. Suppose that precedence constraints among activities restrict the order in which they may be attempted. It may be necessary to complete some before others can be attempted. Suppose that these constraints are represented by some acyclic graph, where each edge represents an activity and each activity can be attempted if and only if all of its predecessors have been successfully completed. The project succeeds and its benefit is obtained if and only if at least one path is successfully completed from a starting activity (one with no predecessors) to an ending activity (one with no successors). In this quite general framework, the optimal (expected utility-maximizing) investment strategy for a decision maker with linear or exponential utility can still be found by assigning to each activity a number called its *index* (by generalizing the failure-probability-per-unit-cost ratio in the preceding example) that can be computed quickly from the cost to attempt, success probability, and precedence constraint data. The optimal decision rule is to *attempt activities in order of decreasing index until either success is achieved or no activities with positive indices remain* [1]. Many other extensions of index policies (also called *Gittins index* policies) have been developed for situations with discount rates, randomly evolving opportunity sets, and relatively sophisticated models of risky projects, such as Markov decision processes and multiarm bandit decision problems [2,3].

OPTIMIZING R&D PROJECT PORTFOLIOS

Optimally sequencing the activities within an R&D project can maximize the expected utility of investing in it, by minimizing the expected time or cost to either complete it, obtaining its benefits, or to discover that this cannot be done, if such is the case. But even after such within-project optimization, the problem of choosing a subset of available R&D projects to fund—often from many proposals—remains. Quantitative approaches to optimizing investment in proposed risky projects to maximize resulting net benefits over time include the following:

- *Combinatorial Optimization Models.* These models search for combinations of select and reject decisions to maximize the net value of the selected portfolio of projects, given budget constraints and possible interactions and dependencies among the projects. Large-scale nonlinear 0–1 programming and mixed integer programming models have been developed for this purpose and are practical with current optimization technology and computational resources [4,5].
- *Improving an Existing Portfolio.* Given any proposed portfolio of risky projects, optimization algorithms can seek to build a modified portfolio with preferred risk-return characteristics by adding or deleting projects and modeling how such additions and deletions shift the predicted (simulated) probability distribution of net return from the entire project portfolio, taking into account interactions among projects [6].
- *Continuous Dynamic Optimization.* In continuous optimization models, explicit optimal investment formulas can be developed and interpreted as equating appropriately defined marginal returns across investments in different projects. This leads to dynamic resource allocation strategies for projects that may have statistically dependent, dynamically evolving market payoffs, assuming that partial investment in a project can generate partial returns [7].

In general, optimization of R&D project portfolios when there are strong interactions among projects (e.g., due to shared subsets of activities or interdependencies among their technical success probabilities and/or market values if successfully completed) provides a rich set of challenging problems for sophisticated, computationally intensive, optimization-based approaches to risk management. Promising approaches include *simulation-optimization* and *robust* and *multicriteria optimization methods* for portfolio selection, together with financial evaluation models that recognize the real option value of risky projects that can be abandoned if they become unattractive. The pharmaceutical and energy industries have developed and applied many such models [8].

As a practical matter, R&D portfolio optimization models can require potentially burdensome input data on project investment opportunities and their interactions (e.g., on overlapping tasks or substitute or complement effects for benefits of different projects), especially since the number of possible interactions grows exponentially with the number of projects. To ease this burden, some recent work has explored the use of approximate (fuzzy) descriptions of potential future cash flows in assessing project portfolio values in a *real options* framework, leading to a fuzzy mixed integer programming model for optimization of R&D portfolios [5].

OWNER VERSUS MANAGER INCENTIVES IN R&D PROJECT MANAGEMENT

In the simplest case of a single minimal path set and no precedence constraints, expected value is maximized by attempting the “most risky” or “most difficult” activities first, that is, those with the highest failure-probability-per-unit-cost ratios. This strategy minimizes the expected cost of discovering that success is impossible, if such is the case. However, rewarding a manager for successfully completed activities may create an incentive to postpone high-risk activities as long as possible, increasing the manager’s expected reward but increasing the expected cost of unsuccessful projects. Projects that should

be abandoned may be continued too long if managers postpone attempting high-risk activities until ones that are more likely to succeed have been completed. Conversely, managers may abandon projects too soon and/or may invest too little effort in making them succeed (from the owner's perspective) when effort and success probability are the managers' private information.

Such incentive problems (which are instances of moral hazard and principal-agent conflict problems) can be largely overcome by evaluating partially completed R&D projects using a *real options* framework and then compensating R&D managers according to these evaluations. More specifically, compensating R&D managers using appropriate adjusted residual income measures (with capital charge rates that are contingent on manager reports of estimated profitability, recognizing that these may be distorted by managers in an attempt to obtain greater compensation) allows an effective separation of R&D investment decisions by owners and effort allocation decisions by R&D managers. Such compensation rules optimally balance incentives to invest in risky R&D against incentives to abandon unfavorable projects in some specific models of owner and manager information and incentives [9].

OPTIMAL INTENSITY OF INVESTMENT IN COMPETITIVE R&D PROJECTS

When a company undertakes R&D to obtain a competitive advantage, time pressure from competition (especially in a "winner takes all" patent and intellectual property environment) may make it worthwhile to invest simultaneously in multiple alternative approaches (e.g., in multiple minimal path sets). This stochastically reduces the time, but stochastically increases the cumulative expenditure, until either success is achieved or no attractive paths forward remain.

Exactly how intensely a company should invest in R&D to maximize expected profit depends on how intensely competitors invest. Hence, quantitative models of optimal investment intensity are often formulated as differential games in continuous time, with

the competing firms deciding at each moment how intensely to invest in R&D based on information available so far. In such competitive R&D models, details of R&D project activities are typically suppressed, and R&D projects are represented by relatively simple models such as functions showing how the cumulative probability (or, equivalently, the hazard function) for successful completion of a project varies with the cumulative amount invested. For example, in the simplest case, each increment of cost or effort creates a fixed probability of successful completion (e.g., successfully finding a new process, drug, or so on); if it does not, then the next increment of cost or effort produces the same probability of success, and so forth. In this case, the probability of succeeding within a budget of t units of cost or effort is just $1 - \exp(-pt)$, where p reflects the success probability per unit of cost or effort. (In more general models, if it is assumed that the most promising approaches are tried first, then p is a decreasing function of t .) In these models, incremental investment purchases incremental success probability, and more rapid expenditures hasten the time either until success occurs, it becomes optimal to abandon the project, or no investment opportunity remains. Typical conclusions from such models are as follows:

- Competitive rivalry increases R&D spending by each competitor when the benefits of the first breakthrough are captured by the firm that achieves it [10].
- If patent protection is incomplete (e.g., reflecting positive externalities from increased knowledge) and/or there are opportunities for licensing so that the benefits of innovation may be shared even by noninnovators, then the effects of competition on the overall pace of innovation are ambiguous. Only some firms may invest in R&D, and social welfare may be either increased or decreased compared to the "winner takes all" situation [11].

Such strategic models of competitive R&D investment and resulting project value complement real options approaches that

treat competitor actions as exogenously specified and then optimize a firm's abandonment decisions (i.e., choice of when and whether to exercise the "option" to abandon). Such models typically assume that remaining cost-to-complete is uncertain and evolves according to a random process as R&D proceeds [12].

CONCLUSIONS

Project portfolio selection, project management, and incentive design problems pose challenging practical applications for quantitative risk management methods. The stakes for effective risk management methods in R&D and other risky projects are high, as the same set of risky project opportunities can lead to either profits or losses, depending on how well the risks are managed through project selection and management.

Although sophisticated quantitative methods for modeling and managing R&D risks (see *R&D Risk Management*) have been developed, as summarized in this article and pursued further in the references, applying such methods in practice, with realistically limited and uncertain data and estimates of potential future R&D costs and benefits continues to be challenging. Yet, it is of great importance in areas such as pharmaceuticals, high technology, and energy, where portfolios of risky projects (see *Managing A Portfolio of Risks*) often drive company value. Therefore, further development of practical methods for R&D risk characterization and risk management decision making will probably remain an active and rewarding area of both theoretical and applied risk management for the foreseeable future.

MANUFACTURING FACILITY DESIGN AND LAYOUT

SUNDERESH S. HERAGU
BANU Y. EKREN
Department of Industrial Engineering,
University of Louisville, Louisville,
Kentucky

INTRODUCTION¹

Structures that are thousands of years old, for example, the Egyptian pyramids, the ruins of the city of Pompeii in modern day Italy, and Harappa and Mohenjo-Daro civilizations of the Indus Valley, suggest that the layout problem has been considered by facility designers for thousands of years. The industrial revolution offers some examples of the importance of layout in designing factories. Henry Ford's assembly line is perhaps the first and significant example of factory layout used as one of the means to achieve higher levels of productivity and efficiency. Although we can cite numerous examples to illustrate the importance of facility planners and analysts placed on facility logistics, the study of facility logistics problems via sophisticated mathematical models did not occur until the introduction of the quadratic assignment problem (QAP) in the mid-1950s by Koopmans and Beckmann [2].

Manufacturing facilities can be broadly defined as buildings where men, material, and machines come together for manufacturing a product or providing a service [3]. It is important to manage a facility in such a way that several, often conflicting, objectives are satisfied. These objectives include producing a product or providing a service at minimum cost, high quality, and in a timely manner; minimizing use of

materials and natural resources; facilitating employee communication and supervision, and so on. To achieve these objectives, a good understanding and analysis of the underlying decision problems are important and necessary.

It is estimated that roughly 8% of the US gross national product has been spent annually since 1955 on new facilities [4]. In addition, expense for modification of previously purchased facilities is also significantly high. Tompkins *et al.* [4] claim that 20–50% of the total operating costs are related to material handling costs. Thus, if we develop an effective facilities plan, not only can these costs be reduced by at least 10–30%, but productivity can be increased as well.

In recent years, there has been a marked increase in the number and types of automated systems. This trend has greatly increased the complexity of system design problems. Designers and users of automated systems have therefore developed new tools to cope with their complexity.

Manufacturing or service system design involves solving a number of design and planning problems arranged in a hierarchy. Some examples are determining the products to be manufactured, services to be provided, manufacturing or service processes to be used, number and types of manufacturing or service equipment capable of performing the required operations, and so on. In the case of manufacturing systems, preliminary process plan development, determining the tooling and fixture requirements, layout of manufacturing cells and machines, material handling methods to be used, and number and types of specific material handling devices capable of performing the required material handling moves are some of the other important design questions that need to be addressed.

Design problems are typically addressed once in 3–5 years or more because it is costly to alter a design decision frequently. For example, once a plant is built in a certain geographic area, it is difficult to justify

¹Some of the material in this section has been reproduced from [3] with permission.

moving the plant to another location within 1 or 2 years of the first decision because the fixed costs would not have been fully recovered within this time period. For example, UPS built its air hub in Louisville, Kentucky, in 1980 to handle packages and letters for domestic and international shipment. When it wanted to integrate heavy freight into the network in 2006, it found that expanding at the same location was more cost effective than moving all its package delivery and heavy freight business to a new facility in another location. Thus, UPS undertook and recently completed a one-million square foot expansion in its Louisville facility. It is thus important to understand the long-term impact of design decisions and consider manufacturing or service activities that are to take place not only in the short run but also in the long run.

FACILITY LAYOUT

An important consideration in the design of both manufacturing and service systems is the physical arrangement or layout of departments. Studies on manufacturing systems indicate that 30–75% of the cost of a product is related to material handling expenses [5]. Tompkins *et al.* [4] mention that material handling activities account for 20–50% of a manufacturing company's total operating budget. Thus, if the departments are arranged optimally, manufacturers can reduce product costs and significantly enhance their competitive position. An arrangement is optimal if no other arrangement can be better with regard to the chosen criterion. In practice, besides minimizing the cost involved in moving goods or personnel between departments, many more factors such as the ones below need to be considered in optimizing the arrangement of departments:

- facilitating smooth flow of people and material by minimizing or eliminating congestion;
- utilizing the available space effectively and efficiently;
- facilitating communication and effective supervision; and

- providing a safe and pleasant environment for employees and visitors.

When designing a facility, the following constraints must be considered:

- Some department pairs must be located adjacently for safety reasons. For example, because of fire hazards, the forging and heat-treatment stations must be next to each other even if relatively few parts flow between them.
- Some department pairs must be in nonadjacent locations. Because the welding station generates sparks that could possibly ignite flammable solvents in the painting station, the two stations should be located as far apart as possible, although there may be a high interaction between them.
- Often, federal, state, and local governmental regulations and hazard insurance company requirements may force departments to be located in specific locations or numbers within the facility. For example, fire-fighting facilities must be strategically located in certain positions, a building of a certain size must have a minimum number of fire exits, and so on. The Occupational Health and Safety Administration (OSHA) requires separate rest rooms for men and women.

Before a facility design problem is addressed, its location must be determined. In practice, there is a multitude of factors that impact location decisions. These include taxes, proximity to source of raw materials, construction cost, transportation system, and so on. Models for determining the location of one or more facilities in a continuous or discrete space are available in the literature (see for example, [3,6]). In this article, we focus on manufacturing facility layout problem rather than its location.

Even though many companies may realize the importance of developing efficient layouts, many of them—especially the smaller ones—do not take this problem seriously. They think that it is too time consuming and difficult to collect and generate data in the format required for problem solving.

BASIC TYPES OF LAYOUT

The first step in the design of a manufacturing facility is to determine the general flow pattern for material, parts, and work-in-process (WIP) inventory through the system. *Flow pattern* refers to the overall pattern in which the product flows from beginning to end. It includes the flow patterns of the product through various stages of processing—from raw material (at the receiving stage) through semifinished product (at the fabrication stage) to the finished product (at the assembly stage). The second step is determining the *type* of layout to be used. We discuss five types of layouts. Although we focus on manufacturing systems layouts, these five layout types are also seen in nonmanufacturing (service) facilities [30].

Product Layout
